ascending node at that point where the earth comes up from below, the descending node when it is plunging down from above. It will be remembered that when the question of terrestrial longitude was occupying our attention it was pointed out that it might begin anywhere: we begin at Greenwich, the French prefer Paris, the Americans Washington, and so on. With regard to celestial longitude, although it also might begin anywhere, yet there is a general agreement among astronomers that the right ascension of stars shall be counted from this ascending node, or, as it is otherwise called, the first point of Aries, where we get the intersection of the earth's plane of rotation with the ecliptic plane of revolution. That is the start-point not only of right ascension for the stars, but of celestial longitude, because it is necessary that we should have a means of determining the positions of stars, not only with reference to the plane of the earth's rotation, but with reference to the plane of the ecliptic itself, and the number of degrees which a heavenly body is observed above or below that plane (such degrees being called degrees of celestial latitude) require to be known in order to determine absolutely the position of any star. With the transit instrument and the sidereal clock the precise angle of intersection of these planes is determined, but it is necessary to know also the precise point in the orbit at which the intersection takes place, before we can use either our transit instrument or our clock for the determination of the precise position of a heavenly body. And now that so much has been said, we can go further with regard to our sidereal clock, and say that it shows oh. om. os. when the first point of Aries is exactly on the central wire of the transit instrument, and that it will come back to that time, oh. om. os., after an interval of twenty-four hours. In that way, by discussing the point of the intersection of the planes, we come to the conclusion not only that the earth's axis is inclined 23½° to the ecliptic plane, but that we have at that point the most convenient starting point both for the right ascension of stars as determined by a sidereal clock, and the longitude of stars, if we choose to define their positions with reference to the ecliptic plane, instead of with reference to the plane of the earth's rotation. It is curious how in dealing with these matters we find that phenomena apparently the most diverse are really bound up in a most intimate connection with each other. In further considering the subject it will be seen that not only do we get these precious start-points from these considerations, but that they bring before us questions of the greatest interest and value to all earth-dwellers, questions that enable us accurately to study not only time as applied to the dealing out of our days and nights, as applied to those changes which take place during the year, as applied to those changes which effect the years themselves, but as applied to those yet greater changes which have probably been going on in this planet of ours for very many millions of years.

J. NORMAN LOCKYER

(To be continued.)

ZOOLOGICAL NOMENCLATURE

ON Tuesday last week a meeting was held in the Lecture Room of the Natural History Museum, where a number of leading British zoologists assembled to meet Dr. Elliott Coues, who is now on a visit to this country, and to hear from him an exposition of the views advocated by himself and the leading American zoologists with regard to the adoption of Trinomial Nomenclature.

Among those present were representatives of many branches of science, and we noticed the following British naturalists:—Lord Walsingham, Prof. Flower, F.R.S., Dr. Günther, F.R.S., P. L. Sclater, F.R.S., Dr. H. B. Woodward, F.R.S., Prof. Traquair, F.R.S., W. T. Blanford, F.R.S., Henry Seebohm, F.L.S., Howard Saunders, F.L.S., Prof. F. Jeffrey Bell, J. E. Harting, F.L.S., G. A. Boulenger, H. T. Wharton, F.L.S., S. O. Ridley, F.L.S., W. F. Kirby, Sec. Ent. Soc., Herbert Druce, F.L.S., W. R. Ogilvie Grant, and R. Bowdler Sharpe, F.L.S.

The chair was taken at 3 p.m. by Prof. Flower, F.R.S., the Director of the Natural History Museum, who briefly opened the proceedings by reading a letter from Prof. Huxley, P.R.S., expressing his great regret at not being able to be present, being prevented by pressure of official business.

The Chairman said:—The subject we have met to discuss is one of extreme importance as well as difficulty to zoologists, for though in so many respects the name attached to any natural object is the most trivial and artificial of any of its attributes, and may hardly be thought worthy of scientific consideration, laxity in the use of names causes endless perplexities and hindrances to the progress of knowledge. I must confess that I feel some sympathy with the young lady, lately quoted in a speech by Sir John Lubbock at the University of London as an instance of hopeless stupidity, who, after listening to a lecture on astronomy, said she had no difficulty in understanding how the distances, motions, and even chemical composition of the stars were discovered, but what puzzled her was how their names were found out. Now, I have often had little difficulty in making out the characters and structure of an animal, and even the functions of some of its organs, but when I have to decide by what name to call it, I am often landed in a sea of perplexity. Yet those of us who work in museums are constantly engaged in cataloguing and labelling, and we are supposed to be able at once to give the correct name to every creature in the collection. I hope that this discussion will help to clear up our ideas upon the subject. With the impartiality due from the chair, I shall not give any opinion upon the merits of the rival schemes to be proposed, at all events not until after hearing the arguments to be brought forward for or against them, and I cannot say that I am very sanguine of being able to do so then. I now call upon Mr. R. Bowdler Sharpe to read a paper "On the expediency, or otherwise, of adopting Trinomial Nomenclature in Zoology."

Mr. Sharpe then read his paper:—I approach the discussion of this subject without the least prejudice either for or against the adoption of trinomial nomenclature. It has been for some time recognised and allowed by zoologists on the other side of the Atlantic, and to a certain extent the principle has been admitted by more than one worker in the Old World, but the presence in this country of one of the most able advocates of the system in the person of that distinguished American zoologist, Dr. Elliott Coues, has recently stimulated the thoughts of many of us as to the wisdom of its adoption for the zoology of the Old World, and it occurred to me that a friendly meeting to discuss the matter with Dr. Coues and some of our leading British zoologists could certainly do no harm, and might be productive of a considerable amount of good. Understanding from Dr. Coues that he would not object to attend a small conference of zoologists on this subject if we desired to talk over the matter, I appealed to many of the latter to appear to-day, and I think that this gathering of British naturalists, under the presidency of our esteemed director, Prof. Flower, is sufficient to show that that there is a considerable amount of keen interest felt in the solution of the question.

It is now more than ten years ago that Dr. Coues, in his "Key to the North American Birds," first began to adopt the trinomial nomenclature which is now so generally accepted by American ornithologists. But until quite recently both he and his coadjutors have been in the habit of inserting the word *var.* before the sub-specific name. At present, however, the system which he adopts is trinomialism pure and simple, and this is shown in the second edition of his "Key," which has just appeared.

Now I can only speak as an ornithologist, and my views must be regarded as purely personal; but I do think that it is good for zoologists in general to learn from the lips of Dr. Coues exactly what the system is which he proposes to adopt for ornithology, and to what lengths it would lead us. I shall listen with attention and respect to the remarks with which any of my colleagues learned in other branches of zoology may favour us this afternoon.

It seems to me that there are certain facts in nature which we all of us recognise as facts, but about the expression of which many of us entertain different views. I propose merely to place before you certain difficult aspects of the question as they present themselves to me, and I shall be glad to have an expression of opinion upon the facts which I bring forward. I would therefore crave permission for a few moments to run over some of the published volumes of the "Catalogue of Birds," and to discuss some changes of nomenclature that might be involved if the trinomial system were to be adopted in a second edition of that work. It will be noticed that in 1874 I recognised the existence of "sub-species" among the *Accipitres*, and I now lay on the table one of the most interesting examples of what I conceive to be a series of sub-species, or representative races, of one dominant form. In Southern Africa we have a small Goshawk called *Astur polyzonoides*, which inhabits the whole of the South African sub-region, but does not, so far as my knowledge goes, extend beyond the Zambesi. In Senegambia and North-East Africa it is replaced by a race called *Astur sphenurus*, in which the colour of the under-surface is much more delicate than in *Astur polyzonoides*. From Central Russia, throughout Turkey, Asia Minor, Persia, and Syria, a large race called *Astur brevipes* replaces the two foregoing sub-species, and forms a third. From Baluchistan, throughout India, and Ceylon, a somewhat smaller form, *Astur badius*, takes up the running, and throughout the Burmese countries, extending to Formosa and Hainan, we have yet another race, *Astur poliopsis*, which is a purer and more elegantly coloured edition of *Astur badius*. This little group of Goshawks has been well worked out, and we may fairly presume that we have the facts before us. Now I should like to know if this is a case where we might adopt the trinomial system, and call these birds

Astur badius,
Astur badius poliopsis,
Astur badius brevipes,
Astur badius sphenurus,
Astur badius polyzonoides.

At present, were I writing about the South African bird or the Abyssinian bird, I should never speak of them as *Astur badius*, which is the name belonging to the Indian bird exclusively, and I am not quite sure that we gain in this case anything whatever by adopting trinomial nomenclature. The same parallel may be drawn with some of the species of *Scops* among the Owls, as may be seen by the series now exhibited, and here trinomial nomenclature might perhaps be employed. Thus the representative races of *Scops giu* would be *S. giu capensis* in Africa, *S. giu pennatus* from the Himalayas, *S. giu minutus* from Ceylon, *S. giu stictonotus* from China, *S. giu japonicus* from Japan, *S. giu malayanus* from Malacca, *S. giu rufipennis* from Madras, and *S. giu brucii* from North-Western India.

In the third volume of the "Catalogue" I have again freely admitted "sub-species," as, for instance, with some Crows, *e.g.* *Corone macrorhyncha* from the Sunda Islands, replaced in India and China by *C. levaillantii*, which extends to Eastern Siberia, but is further replaced in Japan by a large race—*C. japonensis*. In this instance I believe that the trinomial nomenclature could be employed with advantage, for if we spoke of *C. macrorhyncha japonensis* or *C. macrorhyncha levaillantii*, it would convey to us an absolutely definite idea, viz. that these were merely forms of the typical *C. macrorhyncha* with a distinct geographical area assigned to each.

To take another case of a different kind. I place on the table several species of *Chibia* from the Malay Archipelago, and the difficulty which anybody would find at first sight in the separation of these Moluccan Drongos can be explained off-hand by the fact that they are nothing more nor less than representative insular forms of one dominant species. If, therefore, you speak of these birds as *Chibia carbonaria* from the Papuan group of islands, represented by *C. carbonaria assimilis* in the Aru Islands, by *C. carbonaria amboinensis* in Ceram and Amboina, and again by *C. carbonaria atrocærulea* in Batchian and Gilolo, I contend that these names, although long, convey an exact impression of the value of these forms, which are so closely allied as to be almost indistinguishable. A more difficult question arises when we come to treat of the Yellow Wagtails, concerning which, curiously enough, there has been quite a consensus of opinion among some of the German ornithologists that they ought to be treated trinomially. Thus in the "Vögel Ost-Afrikas," by Drs. Finsch and Hartlaub, we find these birds spoken of as *Motacilla flava melanocephala*, &c., and the same phraseology is adopted by Baron von Heuglin in the "Ornithologie Nord-ost Afrikas." Having recently studied these birds, I can only say that I think the employment of trinomial nomenclature by these authors was somewhat premature, inasmuch as, from the showing of the writers themselves, these birds to which they gave trinomial names are not only migratory, but have well-defined geographical areas of distribution. I myself consider that the intermediate forms which undoubtedly exist are due to another and totally different cause, viz. to hybridisation, inasmuch as many of these birds occupy nearly the same winter areas in Africa, and doubtless many of them pair with birds of an allied form on their return to Europe. Thus *Motacilla kaleniczenkii*, which is *M. melanocephala* with a white eyebrow, is probably (although there is no proof of the fact) the latter species with a strain of the white-eyebrowed *M. flava* admixed, as both *M. kaleniczenkii* and *M. melanocephala* occur together.

There is one advantage which we must all admit that the American zoologists possess over ourselves, and that is, that they have a clear idea of the natural geographical divisions of their continent, and their zoology has been studied from many distinct points of view, such as the presence or absence of rainfall, &c., and it only requires a glance at Mr. Hume's essay on the distribution of Indian birds with respect to the distribution of rainfall throughout the Indian peninsula to see how very important is this aspect of the subject. Even in the British Islands there are variations in the size and coloration of some of our resident birds, as any one may learn from Mr. F. Bond, who has devoted sixty years of his life to the study of British ornithology, and who now has one of the most interesting collections in this country. But when we come to study the birds of Europe and the Palæarctic region generally, how small is our real knowledge, and what vast areas are there concerning the ornithology of which we know next to nothing! Great praise is, therefore, due to men like Dr. Menzbier, who has just written the first part of an elaborate treatise on the geographical distribution of birds in Russia; but it will be a long time before we can have in any museum such a series of birds as is possessed by the Smithsonian Institution for any one wishing to study the geographical distribution of the birds of North America. The British Museum is fully alive to the importance of the question, but I find that there is nothing more difficult than to procure from my colleagues in the other countries of Europe a representative set of

the common resident birds of their respective countries. The value of such collections as that which Mr. Seebohm is making cannot be over-estimated.

I have exhibited to-day three distinct illustrations of birds from the Old World where trinomial nomenclature might be employed. In the case of the Goshawks, the Scops Owls, and the Crows, I am not yet certain that my way of treating them in the "Catalogue" as sub-species is not as advantageous as the employment of trinomials. But in the case of the Long-tailed Titmice the circumstances seem to me different, and the adoption of trinomial nomenclature would be a positive advantage, because *Acredula caudata* undoubtedly mixes with *A. rosea* in the Rhine provinces and other parts of Europe; therefore in England, where the *rosea* strain is apparently pure and unmixed, it is advantageous to speak of the bird as *Acredula caudata rosea*, because such a name clearly conveys the idea that *A. rosea* is a form of *A. caudata*, with which it is connected by intermediate forms elsewhere. *A. caudata irbii* would also express the relationship of the South European bird, and *A. caudata trivirgata* the Japanese form.

The case of the Wagtails is not so clear, because we do not yet seem to have sufficient material to work upon. Even here some of the races might be fairly expressed by the employment of trinomials, as *Motacilla flava dubia* for the Siberian and Indian race of *M. flava*. *M. viridis* being a form without an eyebrow, would have a Mediterranean race, *M. viridis cinereocapilla*, while *M. melanocephala* has at least one race, *M. melanocephala kaleniczenkii*, unless the last-named ultimately proves to be a hybrid.

I may say in conclusion that the great difficulty which I perceive in the adoption of trinomial nomenclature, both at home and abroad, lies in the fact that it will open the door to a multiplication of species, or races, founded on insufficient materials, and bestowed by authors who have not sufficient experience of the difficulties of the subject; but I cannot conceal from myself that the code of nomenclature proposed by the British Association and followed by most of us scarcely accounts for the treatment of facts as they have been developed in zoological science since the promulgation of that code, and that before long it will be the duty of British zoologists to attempt its modification.

Mr. Henry Seebohm read the following paper:—The question of a binomial or trinomial nomenclature is not a very simple one. So long as ornithologists were under the delusion that all species were separated from each other by a hard and fast line, the binomial system of nomenclature was sufficient. Now that we know that many forms which have been regarded as species are connected by intermediate links with each other, and that many species present important local variations which cannot be ignored, we are obliged to admit the existence of sub-species as well as species. There can be no doubt that the too tardy recognition by European ornithologists of what might not unreasonably be regarded as the most important fact in ornithology discovered during the present century has been very largely due to a pedantic adherence to a binomial system of nomenclature. Now that we have emancipated ourselves from the fetters with which our predecessors, with the best intentions in the world, cramped our ideas, the question arises, how shall we recognise in our nomenclature the existence of sub-specific forms; by a word, or by a sentence? The ornithologists of America think that a system of trinomial nomenclature will answer the purpose. They have come to the conclusion that the insertion of a third link in the chain which binds us will give our ideas scope enough. Their theory is that the judicious ornithologist will be able to select from the infinite number of steps which form the series of intermediate races which lie between two intergrading species, one, two, three, or even in some cases more local or climatic races which are worthy of being dignified by a name. This theory is on the face of it somewhat illogical. It credits ornithologists with an amount of discretion which their past history does not justify, and totally ignores the inordinate desire to introduce new names which is unfortunately too conspicuous in most if not in all ornithological writers, culminating in the absurdities of a Brehm. That ornithology should be preserved from being Brehmised must be the devout prayer of every well-wisher of the science. On the other hand, the recognition of sub-species by a sentence would be to revert to the customs of the præ-Linnean dark ages of nomenclature, a retrograde step from which all zoologists would instinctively shrink. Members of the British Ornithologists' Union are probably all prepared to admit that a medium course is safest at least for an Ibis (*medio tutissimus ibis*), and, with a very slight modification, I for one am prepared to adopt the American system in spite of its dangers. If no paths are to be trodden in which the indiscreet may err, there is an end at once of all progress.

To point out the modifications which I propose to introduce into the American system of nomenclature to change it from an empirical system to a logical or scientific system, I will take as an example the Common Nuthatch (*Sitta europæa*) and show how the nomenclature of its various races may be made exhaustive, so that the temptation to introduce new names, which appears to be irresistible to the indiscreet ornithologist, may be minimised.

Sitta uralensis, with white under parts, is found in Siberia; *Sitta cæsia*, with chestnut under parts, is found in England; intermediate forms connecting these species together are found in the Baltic provinces. What can be more simple than to call the intermediate forms by both names, *Sitta cæsia-uralensis?* But there is a third species which turns up in China, *Sitta sinensis*, and which is also connected with *Sitta uralensis* by intermediate forms. Never mind; they too can be called by both names, and our series of Nuthatches runs geographically in an unbroken series:—

Sitta cæsia,
Sitta cæsia-uralensis,
Sitta uralensis,
Sitta uralensis-sinensis,
Sitta sinensis.

So far so good; but, unfortunately, two more complications arise. Besides the series running south-west into *S. cæsia*, and that running south-east into *S. sinensis*, two other series run from the central form *S. uralensis*, one running due west and then round by the Baltic into the Scandinavian *S. europæa* (a larger bird, and somewhat darker on the under parts), and a second running due east and then round the Sea of Okotsk into the Kamchatkan *S. albifrons* (a bird much paler on the head, which shades into white on the forehead), so that it is necessary to add four more names to the list, which will stand as under:—

Sitta cæsia is found in Britain, South-West and South Europe, and Asia Minor. It is medium in size, but extreme in the darkness of the chestnut of the under parts.

Sitta cæsia-uralensis (with a hyphen between the two specific names) represents all the forms intermediate between South European and Siberian examples, which occur in Denmark, Pomerania, the Baltic provinces of Russia, Poland, and the Crimea.

Sitta europæa is the Scandinavian form, and represents the extreme of size, whilst in colour it is intermediate between the forms found in the Baltic provinces of Russia and Central Siberia.

Sitta europæa-uralensis comprises all the intermediate forms in Russia which connect the Scandinavian with the Central Siberian forms.

Sitta uralensis is found in the valleys of the Ob, the Yenesei, and the Lena, and combines the small size characteristic of the various Asiatic sub-species of Nuthatch with the dark upper parts of the sub-tropical forms, whilst the under parts are nearly as white as in the Kamchatkan form.

Sitta uralensis-albifrons may be applied to all those intermediate forms found in East Siberia and the north islands of Japan which are not quite so pale on the upper parts as the Kamchatkan form.

Sitta albifrons is found in Kamchatka, and represents the extreme form so far as whiteness of the forehead and under parts is concerned.

Sitta uralensis-sinensis may be applied to the series of forms found in the valley of the Amoor, the island of Askold, and the main island of Japan. They are intermediate in colour between the Central Siberian and Chinese forms, and are scarcely to be distinguished from the Baltic province forms.

Sitta sinensis is found in China, and only differs from the British form in being slightly smaller and in not having quite so much dark chestnut on the flanks.

I have purposely chosen a complicated case in order to show the capabilities of the system, which, if the specific name of *europæa* is always repeated after the generic name of *Sitta*, becomes a compromise between that adopted by the Americans and that which I imperfectly carried out in the fifth volume of the "Catalogue of Birds in the British Museum," and which was originally suggested to me by a conversation with Mr. Salvin. It has at

least the merit of being exhaustive, and differs so slightly from that in common use in America that its adoption does not involve a change in, but only an addition to, the system which in some form or other is destined to supersede the binomial system now rendered inadequate by the acceptance of the theory of evolution.

As an example of the compromise I propose, I add a list of the local races of the Dipper, with their geographical ranges:—

Cinclus aquaticus melanogaster (Scandinavia).

Cinclus aquaticus melanogaster-albicollis sive *Cinclus aquaticus* (West Europe, as far north as the Carpathian and as far south as the Pyrenees).

Cinclus aquaticus albicollis (South Spain, Algiers, Italy, Greece).

Cinclus aquaticus albicollis-cashmiriensis (Asia Minor, Caucasus, Persia).

Cinclus aquaticus leucogaster (East Siberia).

Cinclus aquaticus leucogaster-cashmiriensis (Central Siberia).

Cinclus aquaticus cashmiriensis (Cashmere, South Siberia, and Mongolia).

Cinclus aquaticus cashmiriensis-sordidus (Altai Mountains).

Cinclus aquaticus sordidus (Thibet).

In this system it must be observed that wherever there is a fourth name it is always connected by a hyphen to the third name, and comprises all the intermediate forms between the two. It is somewhat cumbrous, but it provides for the contingency of any intermediate links that may occur. To express it algebraically, it provides not only for A B and B C, but also for A C. It is perhaps the only system which is theoretically perfect, but the question whether its voluminousness renders it impracticable or undesirable is one requiring careful consideration.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

UNIVERSITY COLLEGE, BRISTOL.—A correspondent writes:—This session has been most successful, the numbers of students in attendance being considerably larger than in the two preceding years. Funds are wanted more seriously than ever to complete the building and provide additional accommodation. Nothing has yet been done towards an endowment fund. Mr. E. Buck, M.A., Lecturer in Mathematics, has resigned his position on the staff. The Demonstrator in Physics, Mr. Colman C. Starling, has also resigned his post in consequence of internal rearrangements. The Chair of Geology and Physiology, left vacant by the resignation of Prof. Sollas, has been filled by the appointment of Mr. Lloyd Morgan.

SOCIETIES AND ACADEMIES

SYDNEY

Linnean Society of New South Wales, April 30.—Dr. James C. Cox, F.L.S., vice-president, in the chair.—The Hydromedusæ of Australia, part 2, by R. von Lendenfeld, Ph.D. According to the principles set forth in part 1 of this paper, the Hydromedusæ are classified in a new manner, and the Australian representatives of the first four families in this system are described or referred to. The paper contains descriptions of several new and interesting forms, and in every case an abstract of everything known on the histology of every species is given with references. The most interesting of the new forms is *Eudendrium generale*, the male polypastyles of which show a great similarity to Medusæ. They possess four aboral tentacles in the principal radii, and on these the spermatozoa reach maturity. These tentacular appendages are therefore homologous to the radial canals of the Craspedote Medusæ. Some deductions are drawn herefrom, and the homology of the parts in Medusæ and Polypes described differently to the views expressed by Allman and others. The Umbrella is not homologous to a web between the tentacles of the mouth, but between the generative tentacular processes at the aboral pole.—Revision of the recent Rhipidoglossate and Docoglossate Mollusca of New Zealand, by Prof. F. W. Hutton, F.G.S. The synonymy of all the species is fully given, with, in many instances, revised descriptions and notes on the dentition where known.—Notes on hybridism in the genus Brachychiton, by Baron Ferd. von Mueller, K.C.M.G., M.D., Ph.D., F.R.S., &c. The plant which is the subject of this paper is a beautiful tree of forty feet in height and a stem diameter of one foot, grown at Fern Hill, near Penrith, New South Wales, and is an undoubted hybrid between *Brachychiton populneum* and *Brachychiton acerifolium*. Like most hybrids, the flowers never perfect their seed.—Mr. Macleay read a letter from the Rev. J. E. Tenison-Woods, vice-president of the Society, dated from Perak, February 27 last, giving a long and interesting acount of his proceedings and experiences in the Malacca Peninsula. He had examined and reported on the rich tin mines of the settlement, and the geological features of the whole territory; and he had spent some time in the investigation of its zoological and botanical productions.

Royal Society of New South Wales, May 7.—Annual Meeting.—Hon. Prof. Smith, C.M.G., president, in the chair.—The Report of the Council stated that thirty new members had been elected during the year, and the total number on the roll, April 30, was 494. M. Louis Pasteur, M.D., of the French Academy of Sciences, had been elected an honorary member in the place of the late Dr. Charles Darwin, and Ottokar Feistmantel, M.D., Palæontologist to the Geological Survey of India, had been elected a corresponding member.—The Clarke Medal for the year 1884 had been awarded to Alfred R. C. Selwyn, LL.D., F.R.S., in recognition of his scientific labours in Great Britain and as Director of the Geological Surveys of Canada and of Victoria.—During the year the Society held nine meetings, at which the following papers were read, viz.:—Presidential Address by Chr. Rolleston, C.M.G.—On the aborigines inhabiting the great lacustrine and riverine depression of the Lower Murray, Lower Murrumbidgee, Lower Lachlan, and Lower Darling, by P. Beveridge.—On the Waranamatta shales, by the Rev. J. E. Tenison-Woods, F.G.S., F.L.S.—Further remarks on Australian Strophalosiæ, and description of a new species of Aucella from the Cretaceous rocks of North-East Australia, by R. Etheridge, jun., F.G.S.—On plants used by the natives of North Queensland, Flinders, and Mitchell Rivers, for food, medicine, &c., by E. Palmer (M.L.A. Queensland).—Notes on the genus Macrozamia, with descriptions of some new species, by Charles Moore, F.L.S., V.P.—A list of double-stars, by H. C. Russell, B.A., F.R.A.S.—Some facts connected with irrigation, by the same.—On the discoloration of white bricks made from certain clays in the neighbourhood of Sydney, by E. H. Rennie, M.A.—On the roots of the sugar-cane, by Henry Ling Roth, F.M.S.—On irrigation in Upper India, by H. G. McKinney, A.M.I.C.E.—On tanks and wells of New South Wales; water-supply and irrigation, by A. Pepys Wood.—Additions to the census of the genera of plants hitherto known as indigenous to Australia, by Baron F. von Mueller, K.C.M.G., F.R.S., &c.—The Medical and Microscopical Sections held regular monthly meetings. At the preliminary meeting of the Medical Section this year, the Chairman stated that never during the history of the Section had its meetings been so numerously attended, and that the value of the papers read before it was attested by the fact that so many of them had been reprinted in the Home journals.—The Council has issued the following list of subjects, with the offer of the Society's bronze medal and a prize of 25*l*. for each of the best researches, if of sufficient merit:—Series III. To be sent in not later than September 30, 1884. No. 9. Origin and mode of occurrence of gold-bearing veins and of the associated minerals. No. 10. Influence of the Australian climate in producing modifications of diseases. No. 11. On the Infusoria peculiar to Australia. No. 12. On water-supply in the *interior* of New South Wales. Series IV. To be sent in not later than May 1, 1885. No. 13. Anatomy and life history of the Echidna and Platypus. No. 14. Anatomy and life-history of Mollusca peculiar to Australia. No. 15. The chemical composition of the products from the so-called kerosene shale of New South Wales. Series V. To be sent in not later than May 1, 1886. No. 16. On the chemistry of the Australian gums and resins.—The Chairman read the Presidential Address, and the officers and Council were elected for the ensuing year.

PARIS

Academy of Sciences, June 30.—M. Rolland, President, in the chair.—Remarks on the hygrometric reports from nearly a hundred French stations, yearly published by M. Mascart in the *Annales du Bureau météorologique de France*, by M. J. Jamin.—On the use of formene in the production of very low temperatures, by M. L. Cailletet. The author finds that, when slightly condensed and cooled in boiling ethylene under atmospheric

pressure, this gas is resolved into an extremely volatile colourless fluid, which, in again passing to the gaseous state, yields a degree of cold sufficient immediately to liquefy oxygen. Under these conditions the liquefaction of oxygen becomes one of the simplest operations of the laboratory.—Remarks on the project of creating a so-called inland sea in Algeria and Tunisia, by M. E. Cosson. The author regards as chimerical Dr. Rouire's scheme for converting the Shott Melghir into a marine basin by means of a canal, 145 miles long, communicating with the Mediterranean.—Note on the development of the graphic meth d of representation by means of photography, by M. Marey.—On a new species of Sirenian discovered in the Paris basin, by M. Albert Gaudry.—Observations on the new planet, 237 Palisa, made at the Paris Observatory (equatorial of the west tower), by M. G. Bigourdan.—On the effects of mutual forces: determination of a function represented by a simple curve involving most of the laws of general physics (one illustration), by M. P. Berthot.—Researches on the laws of diffraction of light in the shadow of an opaque screen with rectilinear edge, by M. Gouy. In this paper the author's remarks are restricted to rays diffracted in the geometrical shadow, the edge of the screen being normal to the plane of diffraction containing the incident ray and the diffracted rays.—On certain chemical compounds obtained by means of a gas pile, and of appliances for subjecting the gases to electric effluvium, with tabulated results, by M. A. Figuier.—A method of transforming liquid to dry electric piles, by M. Onimus.—Further researches on the coagulation of colloidal substances, by M. E. Grimaux. Here the author deals first with substances whose coagulation is checked by dilution, secondly with those whose dilution stimulates coagulation.—Researches on the preparation of hydrated chromic acid, and on some new properties of anhydrous chromic acid, by M. H. Moissan.—On the production of the neutral orthophosphate of aluminium in the anhydrous and crystallised state, by M. A. de Schulten.—On a new alcohol derived from the birdlime prepared from the inner bark of the *Ilex aquifolium*; note on a process of the late J. Personne, by M. J. Personne, jun.—Complementary observations on colchicine and colchicéine, by M. S. Zeisel.—On the various processes employed for determining the phosphoric acid in the superphosphates of commerce, by M. E. Aubin.—On the efficacy of vinous yeast artificially prepared, by M. Alph. Rommier.—On the theoretical figures of certain simple substances (lithium, sodium, potassium, rubidium, cæsium) forming a series, by M. L. Hugo.—On a new type of the leech family infesting crocodiles in the Senegambian rivers, by MM. Poirier and A. T. de Rochebrune.—On the fossil cones of the genus Sigillaria in the Carboniferous flora, by M. R. Zeiller.—Note on the assimilation of maltose in the animal system, by MM. A. Dastre and E. Bourquelot.—On the dyspepsia of liquids, by M. V. Audhoui.—Note on a meteorite observed at Concarneau on June 28, 1884, by M. G. Pouchet.—On a meteorite observed at the Trocadéro Observatory on the same night, by M. L. Jaubert.

BERLIN

Physiological Society, June 20.—Prof. du Bois Reymond showed a rabbit with highly-deformed incisors, which had been reared in the Institute. The two lower incisors were several times their natural length, projecting deeply as they did into the nostrils, and were gladiate above and crooked behind. In the upper jaw only one incisor was of about the same size as either of the two under ones. Interiorly it was curved in the form of a semicircle, and rested in a furrow of the under jaw. Mastication, which was rendered difficult by the deformation of the incisors, was effected by lateral movements of the jaws.—Prof. Christiani spoke on the physiology of the brain, connecting his remarks with his former experiments, by which he had demonstrated the existence of two respiratory centres above the medulla oblongata, one of which, situate at the base of the third ventricle, was a centre for inspiration, the other located in the fossa sylvii for expiration. These two centres exercised an influence also on the heart, the one under moderate stimulation producing cessation in systole and retardation of pulsation, the other cessation in diastole and acceleration of pulsation. By the side of the inspiratory centre, and in association with it, Prof. Christiani found a co-ordinatory centre for collective combined movements of the body. On the excision of the brain of a rabbit, if these three centres were left uninjured, and if all considerable bleeding that might prejudicially affect the preserved parts of the brain were avoided, the animal acted entirely as in a normal state: it was able to walk, to run, to spring, to avoid objects in its way, to respond to impressions of seeing and hearing. If, on the other hand, the co-ordinatory centres were injured, these movements all failed: the animal lay on its side, and occasionally showed epileptiform convulsions. Prof. Christiani, having further communicated a series of detailed observations gathered from his experiments with disbrained rabbits, developed the hypothesis he had conceived for himself respecting the function of the brain. According to this hypothesis a large number of energies acted on the brain, in part directly, in part by the medium of the nerves, which, in the ganglia at the base of the brain, were transformed into reflex movements. To this primary circuit the cerebrum formed a kind of secondary circuit into which were derived a large number of the advancing energies, and there hoarded up. If the cerebrum were removed, then all energy was transposed into reflex movement, and consequently disbrained and decapitated animals manifested much stronger reflex movements than did such animals as possessed this secondary derivation. In the higher animals the energy distributed into the cerebrum formed ideas and consciousness, the quality of which might vary, even when the operative sensuous stimulations were completely equal, according to the relative activity of the particular parts of the cerebrum which were stimulated, and according to their configuration. With this conception of the function of the cerebrum Prof. Christiani could not accept the doctrine, advocated quite recently by Hitzig, Ferrier, and Munk, regarding the localisation of the activity of the cerebrum, and in support of his conception he adduced the highly contradictory data that had been accumulated on the sphere of vision. As was known, one portion of the observers, after removal of the sphere of vision, had found blindness to be the result, while another portion, after such an operation, had found that the animals operated on were yet able to see. These contradictions Prof. Christiani sought to reconcile by the assumption that the removal of the sphere of vision produced a stimulation which interfered with those derived from the sensuous organ, and so presented the appearance of the failure of the function.

PROFESSOR TAIT'S "LIGHT"

Light. By P. G. Tait, M.A., Sec.R.S.E., formerly Fellow of St. Peter's College, Cambridge, Professor of Natural Philosopy in the University of Edinburgh. (Edinburgh: Adam and Charles Black, 1884.)

THE issue of Prof. Tait's book on "Heat," recently reviewed in these pages, has been quickly followed by that of his book on "Light."

The book we are told is "not designed for those who intend to make a special study either of theoretical or of experimental optics, but for ordinary students who wish to acquire familiarity with the elements of the subject;" and its author has, as was to be expected, made it most interesting and suggestive.

The first three chapters are introductory and explanatory; we wish more space could have been found for the subject dealt with in Chapter II.—the theory of vision and colour perceptions; students' notions in general are so hazy on these points, and they are not well treated of in most of the books we are acquainted with. They fall between two stools; the physiologist considers them to belong to physics, the physicist to physiology.

In Chapter IV. the usual division of the subject into geometrical and physical optics is made. "For the explanation of the ordinary phenomena of light," says Prof. Tait, "even with accuracy sufficient for the construction of the very finest telescopes and microscopes, it suffices that geometrical optics based on laws *nearly* verified by experiment be followed out to its consequences. The residual phenomena then come in to be treated by the undulatory theory." Geometrical optics then is in the main the subject of the next 140 pages of the book, the remaining 106 pages being chiefly devoted to physical optics.

The geometrical part is excellent, and it, along with the whole book, has been rendered much more interesting by the frequent quotation, when describing some of the most important steps in the subject, of the actual words of the authors, or at all events of a close paraphrase of them. Thus Newton's celebrated discovery of the dispersion of white light is given as a quotation from his letter to Oldenburg. We in the present day gain much by reading the very words of the heroes of science, and learning with what feeble instrumental means they made their great discoveries; there is a tendency, which it is well to check, to think that nothing can be done in the way of scientific observation and discovery without the most elaborate instruments. Fresnel's apparatus in his country-house at Matthieu was the work of the village blacksmith, and Newton needed only his prisms, a measuring tape, and some screens to prove that "light is not similar or homogeneal, but consists of difform rays, some of which are more refrangible than others."

The whole chapter on refraction—Chapter IX.—and specially that part of it which deals with refraction through a prism (§ 129) and the relation between the deviation of a ray and the angle of incidence (§§ 125, 132, &c.) is particularly clear and good. The proof of the law that the deviation of a ray passing through a prism in a principal plane is a minimum when the angles of incidence and emergence are equal (§ 134) is much more elegant than any we have seen before.

But for all this we confess to a strong feeling of regret when we read the statement of the author, quoted already, as to the sufficiency of geometrical optics, a feeling which was greatly intensified when we found how little use was to be made of the all-important law of least time stated for reflection in § 85, or in the more general form in § 82, viz. "If l be the length of the part of a ray which lies within a medium whose refractive index is μ, the sum $\Sigma \mu l$ is the same for each ray of the group between any two wave surfaces;" that is, according to the undulatory theory at least, the time is the same along all rays from one wave surface to another of the same system.

For the fundamental formulæ for mirrors and lenses can be deduced by a simple geometrical method from this law; this Prof. Tait points out, while the method has the great advantage that it can be extended readily to include problems in which spherical aberration is considered. Lord Rayleigh's investigations in optics, published recently in the *Philosophical Magazine*, are a distinguished example of its powers. The full treatment of spherical aberration is of course outside the limits of Prof. Tait's work, but still it would have added to its completeness had the book contained some elementary examples of the use of the method in question. Besides the law is the real link between geometrical and physical optics. That *one* ray of light can exist only when accompanied by other contiguous rays is a fact on which the teacher can scarcely too often insist, and the solution of problems in geometrical optics by the method of least time forms the best introduction to the important principle of interference required in physical optics. Prof. Tait's method is admirable for a book on "Geometrical Optics"; in a book on "Light," however, we look for something more than he gives us on the connection between geometrical and physical optics; and the development of some of the elementary consequences of this law of minimum time seems to us to afford the most suitable opening for considering that connection.

Chapter XII. on absorption and fluorescence, is made specially interesting by the quotation of an account of an experiment of Fox Talbot on anomalous dispersion, made about 1840, but not published till 1870. The method he adopted to obtain prisms of a substance showing anomalous dispersion is very beautiful and ingenious. The account is too long for quotation; we must refer the reader to Prof. Tait's book, p. 156.

The fundamental difficulty of the undulatory theory—the rectilinear propagation of light—is assailed in Chapter XIII., and in dealing with this subject we think that Prof. Tait gives too much credit to that great physicist, Huyghens. He was of course the first to give the undulatory theory definite form, and *if we allow him to make one great assumption*, he explained perfectly correctly the rectilinear propagation, the reflection, and the refraction of light. But in Huyghens' work there is an assumption the importance of which it is impossible to overlook.

"What Huyghens did not see sufficiently clearly," says Verdet ("Optique Physique," tome i. pp. 33, 34), "was why each of the elementary waves is only effective at the

point in which it touches the envelope. He contented himself with saying that the movement which exists over each of the elementary waves must be infinitely feeble compared with that which exists over the envelope," while he remarks that "this must not be examined with too much care or nicety"—"recherché avec trop de soin ni de subtilité" are his words. Nor was Huyghens in a position to give the necessary demonstration, for, to quote again from Verdet, "He never supposed that there was any general relation between the movements of these successive waves, he never combined their effects, and in particular the notion of the constant interference of two sets of vibrations bringing to one and the same point movements of opposite phase is absolutely foreign to him."

Now it is this notion of interference, which is entirely due to Thomas Young, combined with the excessive smallness of the wave-length of light that renders Huyghens' assumption correct.

"It is to Young," says Verdet, "that the honour belongs of having first applied to optical phenomena the principle of interference," and Prof. Tait recognises to the full Young's claims to this distinction; the point on which we would insist is that this principle is needed for the elementary explanation of the rectilinear propagation, the reflection, and the refraction of light, as well as of diffraction and the colours of thin plates; the principle is due to Young, and Huyghens' explanation rests on an assumption which he did not prove.

Prof. Tait regrets in his preface that his book was all in type before Prof. Stokes's "Burnett Lectures" appeared. We will quote a few lines from them bearing on the point. After referring to Huyghens' principle, he says (p. 19):—"This principle does not by itself suffice for the explanation of rays. It proves, or at least appears to prove, too much. It is as applicable to sound as, on the supposition that light consists in undulations, it is to light; and if Huyghens' explanation of rays were complete, there ought equally to be rays of sound, and sound ought to present the same sharp shadows as light."

As Young received in his own day the most unjust treatment at the hands of the leaders of scientific opinion, it is but fair that the full importance of his work should be made clear, and that he should be given all the credit he so richly deserves. In Chapter XIV. Prof. Tait brings out and illustrates with his usual force and vigour the value of Young's principle in explaining the phenomena of the colours of striated surfaces and of thin plates. Young's own attempt to account for the diffraction effects produced by a wire or straight edge was incorrect; it was left for Fresnel in his great memoir on diffraction to show that they too followed as a direct consequence of interference.

It is of course impossible to give without the aid of analysis a full explanation of the phenomena of double refraction, and so Prof. Tait contents himself with showing how Huyghens' construction, combined with the fact that light-vibrations lie in the wave front, enables us to account for many of the observed facts.

When considering the subject of polarisation by reflection (§ 268, &c.), we miss any reference to the experiments of Jamin and others, besides Brewster, on the reflection of light from transparent media. Jamin has shown that Brewster's law requires some modification, for in general there is no angle at which light is *completely* plane-polarised by reflection from a transparent surface. For substances in which the refractive index is about 1·4, an angle of complete polarisation exists, but only for these.

A short chapter on Radiation and Spectrum Analysis concludes the book.

R. T. GLAZEBROOK

OUR BOOK SHELF

A Pocket-Book of Electrical Rules and Tables. By John Munro, C.E., and Andrew Jamieson, A.M.I.C.E., F.R.S.E. (London: Charles Griffin and Co., 1884.)

COLLECTIONS of rules and tables adapted to the wants of civil and mechanical engineers have existed for a considerable time, and now that practical applications of electricity are becoming so many and important, a want has been felt of a useful hand-book for those engaged in this comparatively new branch of engineering. The "Pocket-Book" before us is intended to supply this want, and in many respects it does so very well indeed. It is neat in appearance, handy in shape, and contains much information in the form of tables of practical data, useful rules and recipes, and specifications and directions as to the performance of many different kinds of work.

But although doing good service to electrical engineers by collecting together so much that is useful in the form of practical results, the compilers have, in their endeavour (a mistaken one we think) to render their manual a guide also in points of theory, fallen into many errors which render the book an unsafe one to put into the hands of any one who is capable of being misled in such matters. In the first place there are many—we cannot call them typographical—mistakes in equations given in different parts of the work. As the process by which these equations are obtained is not given, and the formulæ are intended for reference and to be used in computation, there is nothing to warn an inexperienced user of the work of possible danger. The errors might, however, be excused in a first edition if it were not that the formulæ in question are simply inaccurate copies of results given in other works. For example, at pp. 123 and 125, a single glance at "dimensions" is enough to show that several of the formulæ for the localisation of faults in aërial telegraph lines are erroneous, and the same remark applies to the formula given at p. 174 for the calculation of the distance of a fault in a submarine cable from the testing station.

As to the more theoretical portions of the work, we have first a chapter headed "Definitions of Units." This is in great part taken *verbatim* from Prof. Blyth's new edition of Ferguson's "Electricity." An alteration on Prof. Blyth's statement is made on p. 10, and confounds the well-known and perfectly definite velocity v with the velocity which is the proper expression of any given resistance in electro-magnetic measure. Again, at p. 13, v is said to be the ratio of the *electro-static* to the *electro-magnetic unit* of quantity. The "derivation" of the practical units—volt, ohm, ampere—given in the table at p. 13 is a perfect maze of vicious circles, and in the same table the "joule" is given as alternatively "volt × coulomb" and "ampere^2 × ohm,"—the confusion, which would seem inveterate, between work and activity or rate of working. The velocity of light, we may remark, is given at p. 11 as 3×10^{10} cm. per second, and at p. 382 this is given as the "French value" of 192,000 miles per second! Here, as elsewhere in a few cases (the values of g given at p. 42 for example, where, besides, g is expressed as a *velocity*), numbers evidently culled from different sources and supposed to express the same quantity in different units are given without verification of their equivalence. In p. 43 the venerable pendulum formula is terribly misprinted

and g, without its being so stated, is taken in *inches* per second per second.

A chapter headed "Testing of Electric Light Dynamos, Accumulators, and Transmission of Power," given at pp. 176-86, is not at all satisfactory. The tests for the efficiency of a secondary battery are neither clearly nor fully given, and the score of lines devoted to this important subject close with a most remarkable sentence, which we quote:—"The total work done in charging and discharging may also be measured by a suitable voltameter joined up as a shunt to the secondary battery, so as to pass a known fraction of a current through it."

At p. 373 there are two or three misprinted formulas, but in the first line of p. 374 we have perhaps the most extraordinary equation ever given in a work on electrodynamics. The difference of potential at the terminals of a dynamo (a shunt-dynamo we presume is meant) is there stated to be equal alternatively to the product of the current in the field magnets multiplied into their resistance, to the current in the external circuit multiplied into the resistance of the external circuit, and *to the current in the armature multiplied into the resistance of the armature!*

The calculation (p. 345) relative to the electrolytic decomposition of copper sulphate involves also serious theoretical errors. Mr. Jamieson, multiplying together the electro-chemical equivalent of copper and the heat of combination of copper and oxygen, makes the "electromotive force required to deposit copper from a solution of sulphate of copper" to be ·836 volt. In the particular case, not however referred to, of a cell having a platinum anode and copper kathode, this would be the approximate electromotive force required on the cell to produce electrolysis. But the author actually goes on to use this result as the electromotive force required on an ordinary electro-plating bath to effect the electrolysis, and bases on it some conclusions as to the efficiency of a Siemens machine depositing copper in commercial work, or in the stereotyping of ordinary printed matter. In these cases of course both anode and kathode are copper plates, and the calculated electromotive force has no application whatever.

A single remark on another subject we would make before taking leave of this work. In many places where the compilers are under obligations to other authors due acknowledgment is wanting. For examples we may refer to several parts of the chapter on submarine telegraphy, to pp. 369-76 on dynamos and transmission of power, and to part of p. 403, where, by the way, the very serious errors inherent in the method of determining (?) the intensity of a magnetic field by counting the oscillations of a magnetic needle are not alluded to.

In conclusion we have no hesitation in saying that with a careful weeding of the tables, minute verification and correction of the algebraical work, deletion of a good deal of the "theory" given, and lastly, copious references to original sources, both as a matter of convenience to the user and of literary justice, this "Pocket-Book" will be made a very valuable *vade mecum* for electrical engineers. As it is, it will no doubt be found of service, but, as we have indicated, its statements must on several subjects be received with caution. A. Gray

The Non-Bacillar Nature of Abrus Poison. By C. J. H. Warden, Surgeon I.M.S., and L. A. Waddell, Surgeon I.M.S. (Calcutta, 1884.)

This pamphlet is an exhaustive treatise on the nature, physiological and chemical properties of the seeds of *Abrus precatorius*, called Jequirity by the South Americans, and used to cure granular lids. As is now well known through de Wecker of Paris and Prof. Sattler, this popular remedy of the South Americans produces, when used as an infusion and applied to the conjunctiva, severe ophthalmia, in the course of which granular lid (trachoma) is brought to cure. In India it is used by the natives for subcutaneous injection into cattle, wherewith to produce a kind of septicæmia and death. The nature of the poison has been thought by de Wecker and Sattler, and later by MM. Cornil and Berlioz, to be due to a bacillus (the Jequirity bacillus), the spores of which are derived from the air; and, although harmless at first, assume pathogenic properties when grown in an infusion of the Abrus seeds. It has been conclusively proved, however, that this is not the case, that the active principle of the Abrus seeds is present before any contamination with the bacillus could have taken place, and further, that the Jequirity bacillus, when freed from the infusion, possesses no power of producing ophthalmia.

Messrs. Warden and Waddell have carefully examined the chemical nature of the seeds, and they find that the active principle, abrin, is a proteid, closely allied to native albumen, and obtainable not only from the seeds, but also from the root and stem. E. K.

A Text-Book of Pathological Anatomy and Pathogenesis. By Ernst Ziegler. Translated and edited for English students by Donald Macalister, M.A., M.B., &c. Part II. Special Pathological Anatomy, Sections I.-VIII. (London: Macmillan and Co., 1884.)

The enormous success that has attended the first part of this work will, we feel sure, in no way abate with the present volume. Like its predecessor it is a masterly exposition of all that is known concerning the pathological anatomy of the parts treated. In this last volume the special pathological anatomy of the blood and lymph, the vascular mechanism, the spleen and lymphatic glands, the serous membranes, the skin, the mucous membranes, the alimentary tract, the liver and pancreas, are described with great clearness and thoroughness. The subjects are treated in a detailed and systematic way, without incumbrance with self-understood details. The illustrations are very admirable, and while not profuse, are nevertheless thoroughly representative. The bibliography, particularly of the more recent works, is, in the English edition, thanks to Dr. Macalister, a most valuable improvement on that in the German edition. While a help to the learner, it will no doubt prove also a valuable companion to the teacher. E. K.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Late M. Dumas

I have received from M. Pasteur, President of the Committee, a letter informing me that it is proposed to erect a statue to the memory of Dumas at Alais, his native town. The name of Dumas is so prominent in the history of our science that no words of mine are needed in support of such a proposition, and I merely express the hope that many English chemists will be willing to contribute to this memorial. Subscriptions will be received by the secretaries of the Chemical Society, Burlington House, Piccadilly. W. H. Perkin, P.C.S.

The Cholera Germ

The latest enunciations of Prof. Koch from Toulon and Marseilles concerning the relation of his "comma-shaped" bacillus to cholera are so contradictory, that it is worth while to take notice of them.

Koch, as was mentioned in your last issue (p. 237), maintains that the "comma-shaped" bacillus is the cause of cholera; and

finding it in the alimentary canal only, but not in the blood and tissues, of persons affected with cholera, he is necessarily forced to assume that the alimentary canal is the exclusive organ into which the cholera poison enters and in which it has its breeding ground. On the other hand, Koch has ascertained that the "comma-shaped" bacillus is fatally affected by acid. This result, having been established by direct experiment, is naturally perfectly trustworthy, and is, besides, in complete harmony with what is known of other bacilli, both pathogenic and non-pathogenic, which, as is well established, succumb to the influence of acid.

Now, these three propositions, (1) that the "comma-shaped" bacillus is the cause of the cholera, (2) that the alimentary canal is the exclusive organ of entrance of the cholera virus, and (3) that the "comma-shaped" bacillus is neutralised and killed by acid, appear to me to be in hopeless contradiction.

The first two propositions are assumptions, the third is based on direct experiment, and is, as just stated, perfectly in harmony with other observations. If, then, this third proposition be true, the other two cannot be true, that is to say, if it is true—and there can be no doubt about it—that the "comma-shaped" bacillus succumbs to the action of acid, then it cannot be true that the "comma-shaped" bacillus is the cholera virus, nor that the alimentary canal is the sole entrance of the cholera virus. How, we may ask, can the "comma-shaped" bacillus pass unscathed the acid contents and the acid secretion of the stomach? To maintain, as Koch is reported to have done, that in all persons attacked by cholera the stomach must have been previously so deranged that its contents and secretions are not acid must appear to every one who has had any experience during a cholera epidemic an untenable 'proposition. On the one hand, it is known that such a serious disorder of the gastric mucous membrane as the total absence of acidity is of comparatively rare occurrence, while, on the other, in every cholera epidemic numbers of persons become affected with the disease in whom such a gastric condition, antecedent to the infection, can with certainty be excluded. E. K.

The Mountain System of the Malayan Peninsula

SOME new facts with regard to the mountain system of the Malayan peninsula may be of interest to many of your readers. In exploring through the native State of Perak I find that, in addition to the main range, which occupies about the centre of the territory and runs in a north and south direction, there are two other ranges belonging to quite different systems, and, as I think, of different geological age. The first is close to the coast. It is a series of ridges parallel to each other, but detached, having a north-north-east or south-south-west trend. These ridges are of granite, and rise to a considerable height, such as Gunong (Malay for mountain) Inas, over 5000 feet; Titi Wangsu, nearly 7000 feet; Gunong Hijau, 4400 feet, and Gunong Bubu, or Bubor, 5600 feet. The two latter I have ascended. Though they are detached from each other, they form a watershed between the coast and the inland drainage, and thus the River Perak has to drain an immense valley in a north and south direction until it finds an outlet to the south of the Dindings.

To the east of the Perak there is a small range about twenty-five miles long, perfectly detached from the other systems, and having generally a north and south direction, but sending off spurs a little west of south. This also is granite, but on its lower shoulders has thick deposits of stratified limestone, above and below which tin is worked. To the north this range is bounded by the valley of the River Plus, which here joins the Perak, and to the south by the mouth of the Kiuta. The latter river runs in a valley to the east of this range, and where it ceases joins the Perak. To the east of the Kiuta again comes the main range with many peaks over 7000 feet high; Gunong Riam probably reaching over 8000 feet.

The first series of ranges have their origin in the State of Keddah, just where the Malayan peninsula begins to widen out. This widening out is entirely due to this mountain system. The island of Penang is a part of it, and so are the islands called the Dinding Group. Were the coast to subside about 300 feet, we should have a narrow peninsula fronted by a series of large and very elevated granite islands having their longest diameter north-north-east and south-south-west. The second mountain chain has a different direction, and nowhere rises above 3000 feet; but both ranges are rich in tin. The first series has at its base Palæozoic schists, slates, and clays. The second has limestone. The Palæozoic rocks are rich in tin at the junction with the granite. The tin in the second range lies above and below the limestone, and has been derived from the older formation. The Palæozoic clays resemble very closely the gold-bearing slates and schists of Australia. To the south they are nearly denuded away, but in Lower Siam, from specimens I have seen, they are full of auriferous quartz reefs.

It is singular that in this mountain system we have the closest resemblance to the tin-bearing districts of north-eastern Australia. When exploring geologically the Wilde River district in 1881 and the Daintree River in 1879, I found that the sources of the tin were in detached granite mountains or groups of mountains—granite islands, so to speak, much higher than the present watershed of the country, but, being detached from each other, allowed the rivers to pass round and between them. I have referred to the same thing in Tasmania in my account of the physical geology of that country. Geologists in England can say if there is any resemblance to this state of things in the tin-bearing granites of Cornwall. I am inclined to think that we have in these rocks the remains of a former and very ancient mountain system.

I may add that it is a pity that we still find in recent books of high authority the statement reiterated that the highest mountain on the Malayan peninsula is Mount Ophir, near Malacca (4360 feet). Here are the heights of a few in Perak:—Slim Mountains, 6000 or 7000 feet; Titi Wangsu, 6900 feet; Riam, 8000 feet at least; Hijau, 4400 feet; Bubor, 5630 feet; Gunong Rampip, 7800 feet; Gunong Rajah, 6500 feet; besides many others in Keman and Pahang which have not been explored.

Arang Para, Perak, June 2 J. E. TENISON-WOODS

Chalk and the "Origin and Distribution of Deep-Sea Deposits"

IN consequence of Dr. Gwyn Jeffreys' letter, I feel it incumbent, in the interests of geology, to restate the position with regard to the question of the depth of the ocean in which the White Chalk of England was deposited. The cause that led to its deposition over a former land surface was indubitably a great though gradual depression of that area. The process commenced with the Neocomian age, when two seas encroached from north and south, until they were probably only separated by some relatively unimportant ridges or islands to the north of London. The depression seems to have been checked for a long period, but recommenced in the Gault age in a more serious manner. Now, according to Renard and Murray, the *Blue Mud*, with which I assume the Gault is to be identified, if with anything, is formed around shores and in partially inclosed seas, passing into a true deep-sea deposit at a distance from land. The limits of depth at which *Blue Mud* is formed are not stated, but the Mollusca of the Gault, if not indicating a very great depth, are quite against its being a very shallow-water formation. There are several deep-water genera, such as *Neæra, Leda, Limopsis, Cadulus, Dentalium, Eulima*, in it, and I believe that when the smaller Mollusca from it have been reinvestigated by the light of our present knowledge, a far greater similarity between them and deep-water forms will be apparent. The Gault also contains a very large number of Foraminifera and several Encrinites and other Echinoderms, which are not, I believe, characteristic of long-shore deposits; while there is a remarkable absence in it of the more distinctly shallow-water shells that abound in the Neocomian, and it has none of the coarser fragments of rock, 2 cm. in diameter, which are stated in Renard and Murray's paper to occur in the near-shore muds. We must assume a considerable depth of water for the Lower Gault—what depth I would be well pleased to leave to Dr. Gwyn Jeffreys to say. Now, if there is one fact more apparent than another, it is that the Upper Gault represents a deeper sea than the Lower, and therefore that the depression was maintained. The *Blue Mud* is replaced in neighbouring areas by *Green Muds and Sands* with Glauconitic grains which apparently are deposited in similar depths or situations; but the limit of depth at

which either the one or the other is dredged is not stated. A still continued depression takes us through *Green Mud* to the Chalk Marl, which apparently is a true Globigerina ooze[1]; and this passes into a true White Chalk. The White Chalk is the result of still farther depression, for it overlaps the other deposits, and as the great change in the character of the sediment cannot have been due to the shallowing of the sea, and yet must have had a cause, we must conclude it was due to deepening. Its enormous extent and thickness and great purity proclaim it in fact to be an oceanic deposit, and there does not appear to be anything with which it can be compared except Globigerina ooze.[2] The White Chalk of England could therefore only have been deposited under the conditions of depth, or remoteness from land under which the deposit of Globigerina ooze is possible. If Globigerina ooze is not a "terrigenous" deposit, Chalk is not, and it does seem singular that it should be classed as such by Renard and Murray, unless indeed they are prepared to point to an area in which a similar terrigenous formation is taking place at the present day. If genera now confined to shallow-water are present in it, it only proves that there must have been deep-water representatives of those genera in the Cretaceous ocean. This is in fact probable from at least two considerations, the one that the examination of the abyssal fauna is still relatively "extremely slight and cursory," as Dr. Gwyn Jeffreys has so amply admitted in the address he refers me to. It is probable that thousands of casts of the dredge have been made in the littoral zone for one in the abyssal zone, and we are, therefore, not in a position yet to say that any genus may not have representatives in the latter. The second consideration is far more important. Dr. Gwyn Jeffreys states that "all of them (the Cretaceous Mollusca) are evidently tropical forms." Now there is strong evidence from the present distribution, and the deposition of the Chalk, that the sea did not communicate with Arctic seas. Prof. Prestwich, in his anniversary address to the Geological Society, pointed this out in 1871. But even if it had, the Arctic climate during the Cretaceous period was a warm one, and for these two reasons, or either of them, the abyssal depths of the Chalk ocean were probably higher in temperature than they are now, while the temperature of the more littoral zones may have been almost tropical. Heat and cold seem greater factors in the distribution of Mollusca than depth of water. Relatively cold-loving genera or species of genera that could only have found the necessary temperatures then at great depths, may now find suitable habitats in shallow water. The "tropical Mollusca" of the Chalk might for this reason have been able to live at much greater depths when such were warmer, but are of necessity now restricted to those in which suitable temperatures are to be met with; and since these are now all relatively shallow, Dr. Gwyn Jeffreys may be quite right in saying that these extinct species have a shallow-water facies, without our being obliged to accept his inference that the Chalk sea was a shallow one. But if we accept the Mollusca pure and simple as a test of depth, their evidence as adduced is untrustworthy owing to the association together of those of the Gray Chalk and the Irish Chalk band of Kilcorrig. Eliminating these, we have no patelloid shell left but *Hipponyx*, and the Chalk species was completely different in habit to anything living. I do not know the Chalk *Chama* (if the Irish form, this is a limpet) or *Pinna*, and these must be very rare and even pos·ibly drifted shells. The unextinct characteristic genera are in fact reduced to *Terebratula*, *Lima*, *Pecten*, *Armussium*, and *Spondylus*, and of these all but the latter are stated, in the address I am referred to, to have been met with in water 1450 fathoms deep.[3]

It would be impossible to dispose of a question of such importance in a mere letter. My object in writing is to elicit, if possible, the exact grounds on which Messrs. Murray and Renard base their statement that the Chalk was a shore deposit; and it would also be exceedingly useful if Dr. Woodward, Dr. Duncan, Mr. Davidson, and Mr. Carpenter would give their opinions, and the grounds on which they are based, on the probable depth required by each of the Cretaceous groups, respecting which they are the chief authorities. Dr. Gwyn Jeffreys is the only one who has contributed anything definite towards a solution of this most important geological problem, and for this, while believing other conclusions may be deduced than those he has arrived at, I and many other geologists heartily thank him.

J. STARKIE GARDNER

[1] Globigerina ooze is mainly composed, according to Murray, of 40 to 95 per cent. of carbonate of lime, oxides of iron and manganese, and argillaceous matter.

[2] Of reef-building corals there is not a trace either in it or in any contemporaneous formation, and nothing can be more opposed to all evidence than the supposition advocated, it will be remembered, by Wallace in "Island Life."

[3] There are few traces in the English Chalk of any Mollusca except those that possessed calcite shells, and what the rest were like as a group no one can say.

Animal Intelligence

THE following notes of facts observed in New Zealand may be thought of interest; in some way they may serve to illustrate Mr. Romanes' work on "Animal Intelligence": they are submitted without making an attempt to distinguish where they may overlap the fine line between instinct and intelligence. Cases which may show apparent intelligence or the reverse are recorded, that we may arrive at a clearer view of the truth in animal life.

The dog cannot be passed over without mention; he is always to the fore where intelligence is required. Here, where sheep occupy so large a share in the employment of country people, the colly may be seen daily exhibiting its wonderful talents in controlling the movements of its simple charge. Its achievements are too numerous for recital.

Amongst birds we found the quail-hawk (*F. novæ-zelandiæ*), quickly learnt to avail itself of the property of the new settlers; it attacked both poultry and pigeons with the greatest determination directly these foreign birds appeared at the stations and outlying farms. The harrier (*Circus approximans*), more stealthy than the falcon in its depredations on the poultry, perhaps not less destructive, is careful if possible to convey its prey to a quiet spot free from interruption, where its meal can be finished at leisure in security. It found out the use of cornricks and haystacks as mouse-preserves; in some places several harriers might be seen at one time perched on the thatch carefully watching for vermin. It killed the rabbit; the swift-footed hare it found out could be hunted to best advantage in company: several of them would join in the pursuit, wheeling softly with every double of the distressed animal, till, quite exhausted, it lay stretched out in death. The harrier, the gull, the tern, all used to put in their appearance after the large grass fires of former days had swept miles of country; lizards, as they crept from under the stones laid bare by fire, seemed the attraction for all these birds. One autumn, when laid up with rheumatism, lights were brought into the room rather early. I often heard the sound of scratching on the window-glass, and found it proceeded from the efforts of an owl (*Athene, N.Z.*) to secure moths from the lighted-up window-panes; this was repeated for many evenings during parts of the months of April and May, so that I always expected my evening visitor. As a mouser this same species learnt the value of stations near barns and stacks; frequently, many scores of times, have I seen it keeping its solemn watch on a post or rail of the barnyard (see *Zoologist*, 1873, p. 3621). The kakapo or night-parrot (*Stringops*) shows intelligence in its nesting arrangements: the chamber at the end of a long tunnel is covered at the bottom with a great accumulation of excreta; each of these is an inch or more in diameter —the bird is a vegetable feeder—the warmth derived from this mass is secured by the young, reversing the proverb, "It is an ill bird that befouls its own nest."

The kea (*Nestor notabilis*) (see NATURE, vol. iv. p. 489). Its rapid development of a change of habit that led it to destroy sheep has proved very disastrous to many mountain sheep-farmers. It is remarkable that the discovery of the excellence of kidney fat should become known almost simultaneously through a long tract of country; how were beginners instructed to dig their beaks into the wool just above the sheep's kidneys? Horses have been wounded by them in the same part; all this shows a ready means of spreading information. One of the writer's sons snared a few fine specimens, but they very soon became aware of the snare and promptly avoided it. When thrown at, they learn to dodge the stone, just ducking or moving aside. One, imprisoned under an inverted bucket, after a time thrust its strong beak between the rim of the bucket and the floor, turned over the bucket and escaped.

The two cuckoos *Eudanymis* and *Chrysococcyx* offer a problem of peculiar interest as regards migration. The journeys they undertake and accomplish across wide expanses of ocean are amongst the most courageous and trying physical feats in bird history: "as bold as a hawk," "as brave as a gamecock," are proverbs that are befitting; but these birds deserve as much recognition for their adventurous daring.

When either of these species is observed flying, it will be

noticed that the wings are kept constantly in rapid motion; there is no sailing or soaring, gliding through the air on still expanded pinions, but the bird is sustained by determined work. Here in the South Island they are to be seen from the end of the first week in October (further to the north earlier) till March, or even April; the remainder of the year they are not seen in this country. Every part of the islands is known to the Maories; there is no district where they could winter without the fact becoming known. The whistler, or shining cuckoo (*Chrysococcyx*) has been observed in the month of October at Te Wakaru, Chatham Isles, on the beach and in trees exhausted, wet as though from spray; looking at the period of its arrival, and remembering that Te Wakaru is the north-east corner of the large island, it points to the probability that some birds arrive there direct from the warm and distant north, and not from New Zealand, from which the Chatham Island group lies easterly from Cook's Straits about 500 miles. From my own observation I am inclined to believe that with this species the first emigration sets in from the west coast of the South Island of New Zealand about the end of December, as I have observed adult birds in numbers on the sand dunes close to the sea, probably preparing for departure. They make use of the warmest domed nest of our native insect-eating birds, the very rare exceptions afford but two or at most three exceptions in thirty years' observation; in one of these cases an egg found in a nest of the blight-bird (*Zosterops*) approximated in colour those of the dupe; because it was dropped in an open nest? A good example of approximate coloration came under notice in the case of a wounded bittern which was secured and placed under a coop on a piece of grass; she laid an egg of a pale green colour; under ordinary conditions a buff egg would have very well matched the flags of dead sanpo (*Typha*) and faded water grasses, of which its nest is composed. The kingfisher (*Halcyon*) gives a good instance of cleanliness, most necessary in a close nest, containing from five to seven young birds, which remain at home until they can fly well; the entrance of the tunnel to the nest chamber is an upward slope, whilst the eggs are saved from rolling out by a ridge on the edge of the nesting place. In another species the flycatchers (*Rhipidura*) cleanliness is attended to thus: the young back themselves to the edge of the nest to void excrement, which is taken away by the old birds. In the slight nest of the wood-pigeon (*Carpophagus*) cleanliness is provided for by the open work of the structure, so that the dried excreta of the young pass through the spaces of the concave platform. The tui (*Prosthemadera*) enjoys the faculty possessed by the keas, gulls, terns, and many other species, of quickly making known events of interest, as, for instance, in a gorge of one of the great rivers, some cherry-trees rewarded the care of a settler with a fine crop of fruit; a wandering tui found this out, immediately the fruit was attacked by numbers of these beautiful birds, and the crop cleared off. The tuis had to travel some miles from a wood to the cherry-trees. Another instance of the possession of this quality could be witnessed here at the present moment (April 23); from the midst of the massive armed leaves of a variegated aloe has arisen a stately and erect column of blossom reaching upwards to a height of twenty-four feet; its bracts, between thirty and forty in number, laden with rich golden-coloured flowers spread out in formal array. A bell-bird (*Arthornis*) first discovered the richness of the nectaries of this foreign plant. Soon bell-birds and tuis assembled there, a most pleasing sight; their ever-varying motions and postures could be distinctly seen as they flitted about, darted between or hung suspended from the blossoms whilst probing for the honeyed sweets. It has become a floral play-place, a stage enlivened throughout the day with songs and aërial movements; even when the sun has retired behind the western hills, when bees have winged away to distant hives, a bell-bird or two will yet linger, as if to the last minute they would extract some luscious drops.

Since its arrival here in 1856 the blight-bird (*Zosterops*) has shown some notable changes in habit that are in accord with the different conditions under which it now lives in this country: for some years after its arrival it built a suspended, somewhat hammock-shaped nest, in which it laid three eggs; finding from experience that its nest was unmolested by snakes or other egg-robbers, it saved itself much pains and labour by commencing to fix its home in a spray. It, like the goldfinch (*F. carduelis*), freely availed itself of the sheep paddocks, and collected wool as an excellent fabric for nests very readily obtainable; I have seen nests of this species almost entirely constructed of it. One of its familiar names was conferred because it helped to clear fruit-trees of blight and other insect pests; it soon found out the excellent food that a variety of fruits afforded; when trees were netted to secure them from its attacks, it learnt to find out where the meshes of the nets were stretched to their full extent, and there made its ingress and egress to the fruit beneath. The robin (*P. albifrons*) visits conservatories for the sake of insects; we have known them make daily tours round a glass-house, waiting till flower-pots have been removed, when they have eagerly picked up the lurking insects that hid beneath, thus easily earning a hearty meal. The lark or pipit (*Anthus, N.Z.*) for a similar reason will leave uncultivated tussock land to follow the trench made by the gardener's spade, and thus get an abundant supply of the larvæ of the brown chaffer-beetle. I wish to say I do not think this a general habit of the pipit, but I have seen several of the species thus well employed.

The yellow-breasted robin (*P. macrocephala*) and the wren (*Acanthisitta*) will at times use man's buildings for their homes. Nesting material offered to this robin and to the flycatcher have been readily accepted; the latter species made use of some red cotton wool thus put in its way, but worked it up so that it was not seen from the outside. In some cases I have known the last-named neat architect to add a rim to the nest when the young required more room. The chaffinch (*F. cœlebs*[1]) here follows the traditions of its native land, tricks out the exterior of its beautiful nest with lichens, and in many cases supplements this material with fragments of newspaper, for lichen is scarce here; singularly enough this hereditary habit outweighs its sense of concealment, as it places its nest thus adorned on trees without lichen on their bark.

The sparrow (*F. domestica*) is remarkable for the ease and readiness with which it modifies its nesting habits to suit circumstances; in the very heavily topped ti palms (*Cordyline*), where the divergence of the branches is hidden by a massive thatch of long ensiform leaves, sometimes a common roof shelters many compartments; the gregarious instincts of the species are thus carried out at breeding-time; from one of these communities we have taken thirty-one eggs and fourteen young birds at once. On the shelterless "plains" it has been known to modify its old habits by building on the ground, or in heavy road cuttings its nest may be seen in a crevice of the bank, or it builds in some fissure in the cliffs over the sea, just below man's reach; it has taken possession of intricate passages in a heap of coils of fencing-wire; in this last-named instance poultry feathers for lining had to be brought from a mile distance; but then the situation promised security.

The weka (*Ocydromus*), as curious as a magpie, knows the value of a fruit-garden, and that a poultry-yard furnishes eggs. I have seen it pecking at the skin of a dead lamb with heavy blows, and the insects being driven out, it has tugged away at the decaying skin till it has been able to pick up the insects that lay underneath. The dotterel (*C. bicinctus*), red-bill (*Hæmatopus*), paradise duck (*Casarca*), all simulate lameness or distress to lead wayfarers from their young and afford them opportunity for escape or concealment.

The Australian magpie (*Gymnorhina*) has given us some noteworthy instances of its intelligence and resource under difficulties: a pair bred here for some years; one season the young were taken, the wings cut very close. Some impatient creature who could not endure constant and sudden attacks shot the male bird; the young were given away except one poor one, which turned out to be a male. In the following season the old hen was seen building very high, as usual, in a blue gum (*Eucalyptus*); there she was observed feeding young; at length a young one flew from the nest, and, when sufficiently strong on the wing, together with the old hen left the district. Now the poor male with the wings cut was never able to rise from the ground further than by jumping; he had never flown at all, as the stumps of the quills remained in the wings. This was the only male to which the hen could have had access. Whilst the hen was intent on new family cares, the crippled male died. Another pair on the plains, where sticks were scarce, availed themselves of a supply of binding-wire from a patent reaper and binder; the wire cut in lengths furnished an ample supply of lasting material for the nest.

The big gull (*Larus dominicanus*) instantly finds out a dead beast, and makes the fact known; it attacks sickly lambs or sheep that are cast by pecking out the eyes, thus securing its prey by rendering it helpless. I have seen it ascend with a shell-

[1] See *Mittheilungen des Ornithologischen Vereines in Wien*, No. 3, Marz 1884, p. 35.

fish to a considerable height, and drop it on to a shallow in one of the bays, recover its prize, and drop it again and again to obtain the fish within. Many weeks before nesting time these birds visit the old breeding-stations, as if to estimate the repairs that will be necessary to render the old nests available; this visit is carried on with great clamour. A cormorant (*Graculus*) was shot at and wounded at a tench-pond at Rockwood; it kept in the pond; it could not fly. A dog was sent in to fetch it out; it faced the dog resolutely, which turned tail; this part of the animal was immediately seized by the cormorant, who was in this singular manner towed ashore; but its odd feat did not serve to save its life. The fantail flycatcher (*Rhipidura*) enters houses in pursuit of flies glancing from room to room; it soon clears them of these insects. Dr. Otto Finsch in his "Ornithological Letters from the Pacific" mentions this habit as witnessed by him here.

Amongst hymenopterous insects the Sphegidæ offer instances of intelligence. A species of Sphex with orange-coloured body deposits the benumbed or torpid bodies of spiders in some crevice for future use. An individual of this species had its hole in a dry corner beneath the plate of a long veranda. One day I observed it dragging a victim along a gravelled walk that was parallel to the veranda; the small stones and grit made its progress very difficult. After very trying struggles with these impediments it displayed a remarkable degree of intelligence, by which it gained its ends. It altered its course and made for the veranda, ascending the smooth, painted board that adjoined the gravelled walk. After slowly traversing seven inches of perpendicular it came to a rounded beading which projected outwards. Now came its supreme moment of physical exertion. The body of the spider apparently was too heavy to render the aid of wings available. After several pauses in its progress it slowly yet surely surmounted the difficulty presented by the projecting beading, gained the level boards of the veranda, along which it travelled rapidly with its burden, which it sometimes dragged, sometimes pushed before it. By the expenditure of great exertion in surmounting the beading it gained a smooth and level run to its home of thirty-nine feet. A species of Mantis remains so still on a leaf of its own colour that it is difficult of detection; it takes its prey by surprise, darting forward its armed fore-limbs with a sudden spring.

I have had in the shrubbery a colony of Phasmæ for the last nine or ten years. In all that time they have remained almost entirely on one tree (*Oleurea Fosteri*). Yet, accustomed as I am to them, they place themselves so much in a line with the sprays of the tree that they are difficult to discern; in drizzling north-east weather some dark markings appear along their bodies, which match the wet sprays wonderfully. It should be noted that the Australian magpie, the halcyon, and many insect-eaters have for years bred and lived in the trees or banks near them; yet they still survive, notwithstanding the proximity of these enemies to insect life.

T. H. POTTS

Ohinitahi

THE following extract from a letter which I have just received from Mr. J. H. Wheelwright appears to me of sufficient interest to publish in your columns, as it serves to give, among other things, a good deal of new and first-hand information on one of the most important branches of comparative psychology, viz. that relating to feral and partly wild domesticated animals.

GEORGE J. ROMANES

Cattle very easily relapse from domestication. They become distinctly nocturnal in their habits; their sense of smell is very strong. Wild cattle degenerate rapidly in size, owing, I think, to the persecution of the young heifers by the yearling bulls. In three or four generations in Queensland wild cattle revert to one uniform colour, a dun colour or dirty brown with a yellowish stripe along the spine, and a yellow nose. Wild cattle will remain all day long concealed in the depths of thick, inaccessible jungle—"bungalow scrub" or "mallee" we call it in Australia—issuing forth at night to graze and drink, and it requires much care and very hard riding to entangle a few of them among a lot of quiet cattle and secure them. Australian cattle have many habits their domesticated progenitors have lost. For instance, in summer-time grass becomes very scarce near the rivers, and the cattle walk in from their feeding-grounds as much as ten or fifteen miles to water, marching in long strings and feeding back again. Young calves of course could not do this. I have frequently noticed two or three cows far out on the plain, who, when they saw me, would lift their heads and watch me. Presently I would come across a kind of *crèche*, a mob of perhaps thirty little calves all lying snugly in some small, sheltered dip of the ground, left there in charge of the sentinel cows by their mothers who had gone in to water. Now as soon as these calves saw me they would try to hide—do it very well too, under any little bush there might be handy, and lie close until I got off my horse and touched one; then he would jump up, and, no matter how young, make a staggering charge at my legs. He would give a peculiar cry at the same time, which would bring the guardian cows in at a full gallop and give me reason to mount at once. Cattle have extraordinary *homing* power; so have horses. Cattle recognise *individuals* in a very extraordinary way. I have had considerable experience in droving large herds, say 1000 or 1200 head, long journeys extending over many months. I have been struck with the fact that, a week after that herd has been travelling, every beast in it seems personally acquainted with every other: that is, if a strange cow or bullock were to join the herd, that cow or bullock would be immediately expelled. When a herd is travelling thus, each beast in a very few days takes up his position in the mob, and may always be found in the van, the rear, or on the right or left wing, the strongest cattle leading. That cattle and horses can *smell* water is a delusion. Cattle and horses always have their particular friends; at night when cattle are *camping* on a journey, there is always much bellowing and fuss until certain *côteries* of friends get together and lie down comfortably. A beast blind of, say the *left* eye, always travels at the outside of the *right* wing of the drove. A beast that has been scratched sufficiently to draw blood will be hunted and pursued by all the rest. Cattle have a habit of appointing certain *camps* or *rendezvous*, where, on any alarm, they congregate. Half-wild cattle are sometimes very difficult to drive off these camps. Wild cattle are singularly clever in concealing themselves, as are all wild beasts, and will hide in half a dozen little bushes no one would suppose would hold a calf.

Wild "dingo" puppies, taken away from their mothers, are easily reared, but never lose their inborn savagery: they are not to be trusted near poultry, sheep, or cats. The chief difference between them and their civilised brethren is, if, say a collie pup misbehaves himself and is kicked, he yelps, sticks his tail between his legs, and runs away; whereas his wild brother, with his tail erect as that of a Dandie Dimont terrier, snaps viciously at the foot which kicks him. I have owned a pure-bred dingo ("warrigal" we call them) which ran with our kangaroo dogs, and the dog would worry one of his own kind with as savage a zest as would any of the great powerful hounds with which he had associated himself. As to feigning death, I think the Australian "dingo," or "warrigal," a good case in point. We once ran a wild dog with three powerful kangaroo dogs, noted for their killing powers; they caught him, worried him, and he lay for dead; at any rate the hounds thought he was done for; they lay down quite contentedly to regain their wind. We cut off the warrigal's brush, and he gave no sign. Just as I was getting on to my horse, I saw the supposed corpse open one eye. Of course we put the thing beyond a doubt. A kangaroo dog has been known to run down a dingo bitch at heat, line her, and then kill her. The worst and most dangerous wild dogs in the Australian pastoral districts are *half-bred ones*. Kangaroo dogs should be, I think, about three-quarters greyhound—the rest either mastiff or bull-dog; such a dog should be able to catch and kill almost anything.

A doe kangaroo, when hunted and hard pressed, will throw the young one out of the pouch into any handy clump of scrub or tussock of grass. The "Joey" accepts the situation, and makes himself as small as ever he can; in fact, in looking for him, all you ever can see are his bright eyes. Young kangaroos seem to possess exactly the same instinct as the calves of wild or semi-wild cattle, that of concealing themselves. Young kangaroos soon adapt themselves to circumstances, and make themselves comfortable at the bottom of the pocket of a jacket.

I remember that once upon a time, about 1856, we caught a brood of wild ducklings, which we took home and put under a hen. These ducklings, not one of them fledged, walked a mile and a half along a very dusty road to the place whence we had taken them, and rejoined, as I hope, their progenitors. Our black boys tracked them.

Diffusion of Scientific Memoirs

IN some of the numbers of NATURE which have recently reached me I find that Prof. Tait has broached a subject of

extreme importance to societies interested in the distribution of their publications, and in the receipt of publications from kindred bodies. Although I am connected with a small society which has hitherto only enjoyed an ephemeral existence, I trust that a brief account of my experience in the distribution of publications may have a little value. Early in 1883 more than 250 copies of our publications were distributed amongst the leading societies and libraries throughout the world. On my exchange list I now have 271 names; I also send to about 100 members of the Society. A few copies of our publications have been sent to persons who have made seismology a specialty. With each volume there was inclosed a printed form to be filled up and returned, both as a receipt and as a statement of other volumes which might be required. The institutions to which volumes were sent were as far as possible selected as having an interest in scientific investigations. Especial care was taken to forward volumes to institutions established in earthquake-shaken or volcanic regions, as for instance to many parts of South America, New Zealand, Central Siberia, Iceland, &c.

In many cases our receipts were returned. In others societies returned their own special forms. A few societies sent us their publications in return. One society very kindly made a collection of earthquake literature for us. Several others made special applications for particular volumes to complete the series of our publications. *In about half the cases, however, I find that no notice whatever was taken of our gift.*

For example—

For 34 volumes sent to institutions in England 17 receipts were received.
" 40 " " " Germany 22 " "
" 49 " " the United States 31 " "
&c., &c., &c.

One result has been that our distribution list has been reduced. In one or two instances, where I know that earthquake literature cannot fail to be acceptable, the omission to send acknowledgment has been overlooked, and I continue to post our publications.

No doubt many societies publish lists of presents. These may be useful to the members of such societies; but they are valueless to donors who are not favoured with such publications.

The fact which is most to be regretted is that these omissions have resulted in many libraries not being *au courant* with the latest information.

Now supposing that the publications in question have any value whatever, it is natural to seek a cause for this state of affairs.

In many instances the omissions may be due to negligence, whilst in others they may be due to institutions having failed to establish a system for their correspondence.

From my own communications with various societies it is evident that many of them neither possess forms for routine correspondence nor have they the means for facilitating reference to ordinary or extraordinary correspondence. Sheets of plain notepaper, envelopes, pens, ink, and a few postcards constitute the business equipment.

Those societies which possess forms for the acknowledgement of presents, &c., often sacrifice fivepence for the postage of an elaborate document where a wrapper or a three-halfpenny postcard, although wanting in formality, would attain the same result. Although learned societies are not institutions where business is a specialty, many of them might possibly derive benefit by the adoption of more business-like methods. At present it would appear that there are many institutions which are as equally indifferent to the circulation of their own publications as they are to receive those of others.

JOHN MILNE,
Hon. Sec. of the Seismological Society of Japan

Tokio, June 7

Suicide of Snakes

THE letter of Edward F. Hardman in NATURE (vol. xxix. p. 452), with reference to the suicide of black snakes, recalls an incident which I once witnessed; I was quite small, but my memory of the strange occurrence is very clear and distinct. It was in the State of Illinois, when at that early day a short, thick variety of rattlesnake was very numerous, so much so that the State acquired an unenviable reputation in the older parts of the Union. Farmers in "breaking prairie," as the first ploughing of the prairie sod was called, would kill them by dozens in the course of a single summer. They were very venomous, but owing to their sluggish nature and their rattle, which was always sounded before an attack, but few persons were bitten by them. Moreover, there was little danger of death if proper remedies were applied at once.

I was one day following one of the large breaking ploughs common at that time. It was drawn by five or six yoke of oxen, and there were two men to manage the plough and the team. As we were going along, one of the men discovered a rattlesnake, as I remember about twelve or fourteen inches in length. They rarely exceeded eighteen or twenty inches, so that this one was probably about two-thirds grown. The man who first saw it was about to kill it, when the other proposed to see if it could be made to bite itself, which it was commonly reported the rattlesnake would do if angered and prevented from escaping. Accordingly they poked the snake over into the ploughed ground, and then began teasing it with their long whips. Escape was impossible, and the snake soon became frantic at its ineffectual attempts either to injure its assailants or to get away from them. At last it turned upon itself and struck its fangs into its own body, about the middle.

The poison seemed to take effect instantly. The fangs were not withdrawn at all, and if not perfectly dead within less than five minutes, it at least showed no signs of life. That it should die so quickly will not seem strange if it is borne in mind that the same bite would have killed a full-grown man in a few hours' time.

The men watched it long enough to be sure that it would not be likely to move away, and then went on with their work. I trudged around with them for an hour or more, and every time we came where the snake was I stopped and looked at it, but it never moved again. In this case I do not remember that the snake had been injured at all. I have often heard of rattlesnakes biting themselves under such circumstances, but this was the only case that ever came under my observation.

Ongole, India, June 17 W. R. MANLEY

Sky Glows

As we appear to be having a return of the gorgeous sunset phenomena with which we were favoured towards the end of last year, a brief mention of two of the most brilliant displays that I have recently had the good fortune to observe may be of sufficient interest to place upon record in the pages of NATURE. The "after-glow," though very brilliant, has not of course attracted the attention it would have done, on account of the twilight; if it had not been for that circumstance, I think the recent displays of the phenomena would have been quite as gorgeous as those of last year. It would certainly have been so in the case of the "after-glow" on June 22; the "glow" on that evening at nine o'clock reached an altitude of 45°, and extended from the north to the west-north-west point of the horizon. For an altitude of about 20° the glow was of a beautiful crimson tint; above that altitude it was of a pale pink fading away gradually towards the edge to a pale orange. On that evening the reddish glow was not confined to that part of the horizon where the sun had gone down, but extended over the entire sky from the west to the east, the whole celestial vault, which was quite free from clouds, appearing to be slightly tinged with red. So conspicuous was this redness of the sky that a lady friend remarked—before her attention had been called to it —"How red all the sky is."

On the 7th inst. the "glow" equalled in brilliancy, though not in extent, the display above described. At 8h. 45m. p.m. it reached an altitude of about 30°, and extended from the west-south-west to the north-north-west point of the horizon. The redness of the whole sky, which was so noticeable on the former occasion, was wanting on this. On both occasions the "glow" was not visible for more than an hour and a quarter after sunset.

Dalston, E., July 12 B. J. HOPKINS

MANY of your correspondents have referred to the "remarkable appearances of the sky" at sunrise and sunset last year, but I have not observed any reference to the following:—On the morning of November 30 I was on my way from Basle to Calais by the St. Gothard mail train, and observed the whole eastern sky become lit up as though there were a splendid sunrise; the larger print of a newspaper was easily readable at the carriage window. On referring to our watches we found it was 5 o'clock by Basle time. During the next half-hour every trace of the phenomenon gradually vanished. FRANK PETRIE

Fireball

READING W. G. Smith's remarks on lightning in last week's NATURE (p. 241), recalls to my mind a ball I saw during a storm in the autumn of 1881. The storm had lasted some time, and I sat reading a little back from an open window but facing it. Suddenly it became so dark that I could no longer see. I dropped my book and looked out. A ball of fire was passing through the window into the room. It moved very slowly onwards and downwards towards me, and became almost stationary over my book. At first I thought it rested upon it, but I soon saw it was moving slowly across. Having passed over the book, it turned in the direction of my hand, paused just beneath it, and then sank towards the carpet. At this instant a peal of thunder crashed over the house—it was the very loudest I have ever heard.

Butterflies as Botanists

THERE can be no doubt, as pointed out by Fritz Müller in your last issue (p. 240), that the habits of insects often indicate affinities in plants. There is doubtless a strong affinity between the Solanaceæ and Scrophularineæ; the small oval pollen is almost identical in both. The habits of fungus parasites sometimes disclose similar relationships, often more real than is at first apparent; we have an example of this in the fungus of the potato disease, *Peronospora infestans*. This parasite is almost peculiar to the Solanaceæ, being especially destructive to Solanum, Lycopersicum, and Petunia, but at times it invades the Scrophularineæ and grows on Anthocersis and Schizanthus. It is not common to find one parasitic fungus attacking the members of two natural orders of plants, but other examples could be given.

W. G. S.

A Cannibal Snake

ABOUT eighteen months ago, just previous to my leaving India, at Devalah in the Wynaad, the horsekeepers chased and killed a large cobra, 5 feet 4 inches; previous to death it was thrown down in front of the door of our house, when, after a good deal of twisting and wavy contortion of the body, it disgorged a small rock snake over 4 feet in length. I had heard of the same thing before in India, so that I do not think cannibalism in snakes is so uncommon as Mr. Evans thinks.

FOURTH NOTE ON THE ELECTRICAL RESISTANCE OF THE HUMAN BODY

IN my communication to NATURE (vol. xxix. p. 528) I described the use of alternating currents and the telephone for the above purpose, and promised to endeavour to obtain at least an approximate measurement of the E.M.F. developed in the secondary coil of an induction apparatus. This promise I now propose to fulfil. But before proceeding to the special subject of the present note, I should wish to draw attention to a paper which appeared on the 15th of the same month in the *Asclepiad*, by that able experimentalist Dr. B. W. Richardson. He therein describes not only experiments made with the large induction coil of the Polytechnic, but also others made as early as 1868 in conjunction with the late Mr. Becker, the object of which was to obtain a measure of the resistance of animal structures.

"The results," says Dr. Richardson, "were not fully satisfactory. They were variable even when the conditions under which the experiments were made were entirely the same. This variability we found to be due to decomposition of the animal substance, a decomposition which, however feeble the battery, was sufficient to destroy the precision we desired to obtain." Putting the more recently coined word "polarisation" for decomposition, this expresses exactly the difficulty described by me in my first note. "It was, however, possible," says the doctor, "to make out that blood conducted better than any other structure of the body, and better than water." I can now fully corroborate this excellent observation, and perhaps extend its application.

Physiological and even pathological fluids, such as the serum of dropsy, conduct far better than muscle, bone, and nerve. One instance out of many may serve. In the very first case recorded in my communication to NATURE (vol. xxviii. p. 151) the lowest resistance obtained from foot to foot was 2300 ohms. The patient was then very emaciated, but quite free from dropsy. Towards the end of the case, which after death proved to be one of ulcerative endocarditis, as I had considered it to be during life, slight but distinct dropsical effusion in the lower extremities set in; the resistance sank at once to 700 ohms, and I had to discontinue my observations from the evident change of electrical conditions. I have since verified the same fact many times, and on it I partly found the belief, already several times stated, that "the human body, in spite of its large amount of liquid constituents, follows a similar thermal law of resistance to that influencing solid conductors, though in a very much higher ratio" (NATURE, vol. xxviii. p. 152).

Dr. Richardson does not seem to have attempted to determine the resistance of the living body, which Du Moncel, in 1877, did, and with fairly accurate, if unpleasant, results (NATURE, vol. xxix. p. 528). On the discovery, however, in 1879, of Prof. Hughes's electric balance, he resumed his observations, this time with an alternating induction current, though he does not himself notice the important change. His results are unfortunately taken in arbitrary units on the graduated scale of 200 parts originally applied to Prof. Hughes's instrument. If there is any way of reducing these fictitious to absolute values, my work will be both lightened and assisted by a proved observer. Blood-clot and serum, white and gray nervous substance, muscle, bone, coagulated albumen, gelatine, and pus were all tested. Some of the results were excellent. For instance, fat, which by one experimenter has been stated to increase the conductivity of the body, is found by Dr. Richardson, as I also have found it, to be an absolute non-conductor. It is almost unnecessary to say that, with so skilled a chemist and physiologist, all proper temperature corrections and other similar precautions were most strictly observed.

I can now proceed to the main topic of my present note. On receipt of the Wurzburg dynamometer it was put in adjustment, and a strenuous effort made to compare the indications given with a constant and an alternating current, to both of which it is sensitive. But the movable suspended coil made of an ivory core, with a double weight of silk-covered copper wire, hung by a platinum hook, and dipping by its other termination into a vessel of strong sulphuric acid by means of a platinised platinum plate, is very heavy; takes a long time to get to its full deflection, thus allowing the battery to run down sensibly, and, what is worst of all, has a tendency to "integrate." By this I mean to sum up, by its mechanical inertia, a large number of small, intermittent pulls as given by the reversed current, into an almost identical deflection (less, of course, losses) with that given by the one steady pull of a continuous current. In spite of its beautiful workmanship, it had to be discarded for the present research. Somewhat in despair, I fell back on a similar instrument, shown by me at the Oxford meeting of the Physical Society in June 1882, and there heavily abused. The moving coil in this is made of silk-covered aluminium wire to insure lightness, and the bifilar suspension is made of the silver-gilt wire used for military epaulettes and facings. It is the work of my own poor hands.

Herr Obach then stated, and the statement was repeated in your columns, that this material had already been used by Messrs. Siemens for their "dust-recorders," but had failed by difficulty of making contact. On testing my little toy, I found its resistance had not

altered in twenty-five months one fraction of an ohm, and that it moved briskly up to its maximum, standing there quite long enough for a good observation. Indeed, in spite of its condemnation by a jury of experts over two years ago, it was still so lively that I thought it better to check extra swing by a small platinum paddle 1 cm. square moving in sulphuric acid.

On a metre scale, at one metre distance, the reflected image in a telescope gave ·365 mm. deflection[1] with the whole induction current from Prof. Kohlrausch's metre-bridge, as described in my last note.

The object now was obviously to obtain an independent measure of the actual E.M.F. to which this deflection was due. The quadrant electrometer, or some other delicate potential measurer, of course suggested itself. A trapdoor portable, kindly lent me by Prof. McLeod, refused to take notice of my wretched little currents, limited as they are by human susceptibility. I do not possess a quadrant, nor will the Royal Society, though twice asked, lend me one. Here again my friends at Cooper's Hill came to my rescue, and I have to express my thanks, not only to Prof. McLeod, but also to Prof. Stocker and his excellent demonstrator Mr. Gregory, for their assistance. With my Kohlrausch induction bridge in a big bag I journeyed to Egham, and thence on foot to Cooper's Hill.

The formula to be made use of was obvious. It is given in Prof. Adams's Cantor lectures, and has been kindly verified for me by Prof. Hopkinson. In it the needle is connected with one pair of quadrants, so that $V_3 = V_1$. In this case—

$$\text{Deflexion} = \frac{k}{2}(V_1 - V_2)^2.$$

Prof. Adams has since shown me a different, and perhaps better, way of working, which I intend to make use of in the future. It was found that the two fine quadrant electrometers at Cooper's Hill College were unavailable; the one given by Lord Salisbury not admitting of the needle being placed in connection with either pair of quadrants, the other being disabled by some casual contact. We therefore with heavy hearts made a last struggle with the old Elliott pattern and single quadrants. This succeeded admirably, and on a mean of the four best out of six observations, we obtained a deflection of 107 with the intermittent current. "In order to be quite sure," Mr. Gregory wrote to me next day, "of the true value of the mean deflection we obtained, I have executed measurements with different numbers of cells. In these, the negative pole was to earth, the positive being connected at will to either pair of quadrants, and the needle also at will to either pair, giving four readings for each observation. I give only means, which agree well.

E.M.F.	Defl.	k
21 volts ...	32·75 ...	·149
29 ,, ...	63·75 ...	·151
47 ,, ...	161·75 ...	·146
	Mean	·1486

k was calculated from the formula

$$\delta = \frac{k}{2}(V_1 - V_2)^2.$$

By calculation, using the mean value of k, the E.M.F. to give a deflection of 107 came out 38. By observation, using an E.M.F. of 38 volts, the deflection was 107·25. This agrees so well with the calculated value that it will be easy to evaluate the E.M.F. corresponding to any deflection by the above formula."

The effect of rapid alternations seems to be to lessen the deflection, though Mr. Glazebrook stated, in a paper read before the Physical Society, that with between 10 and 120 contacts per second the result, in charging a condenser, was not perceptible.

[1] The bridge arrangement being entirely disconnected.

On the whole therefore, though I agree with Mr. Gregory that we have not obtained a measure of the maximum E.M.F., but only an integration, disregarding sign, the approximation is, I hope, superior to any made before, and affords a good general basis for farther work.

W. H. STONE

GAS-BURNERS[1]

THE economist who wished to point the moral of a healthy competition in industrial commerce could scarcely find a better instance to his hand than the progress made by gas illumination under the impetus given in the last few years by the rise of electric lighting. It is not overstating the case to say that greater improvement in the use of gas has been made since Jablochkoff introduced his electric candle than in the previous sixty years' history of gas lighting. Compared with the recent development of invention, the long period of non-competition appears almost stagnant. With the introduction of electricity arose a popular demand for "more light." With a new illuminant competing for favour, consumers growled more openly at "bad gas" and high gas bills. Each advance of the electric light was greeted with acclamations by the popular voice, shareholders began to tremble, and gas shares came down with a rush. It was time for gas managers and manufacturers to bestir themselves. The happy days of a monopoly in light seemed over. The consumers have reaped the benefit. Under the stimulus of competition the price of gas has been lowered, impurities have been cut down. Some half a dozen years ago the great London Companies were endeavouring to prove before a Parliamentary Committee that coal-gas could not be purified from bisulphide of carbon without creating such a nuisance as to be intolerable. Their object was to do away with the lime purifiers, made necessary by the regulations of the Gas Referees, and to use only oxide of iron. Since the advent of the electric light not a word has been heard about the impossibility of purifying coal-gas by lime. On the contrary, every effort is now made to supply gas as free from sulphur as possible. But while the gas has thus been improved in quality and lowered in price, a still greater improvement has been effected in the methods of burning it. By the application of the regenerative principle to gas-burners, the illuminative value of coal-gas has been doubled.

But in spite of the great advances made in gas-burners, the public have by no means yet reaped the full benefit. Owing to the carelessness of gas-fitters and the ignorance of consumers, the great majority of those who light their houses by gas waste at least 20 per cent. of their gas as an illuminating agent. If the flame smokes, or flickers, or gives a poor light, most people put it down to "bad gas," when in reality the burner is unsuitable, or worn out, or the supply pipes (nearly always too small) are choked. To all who burn coal-gas in their houses, and are troubled with "bad gas," we can heartily recommend "Gas-Burners, Old and New," by Owen Merriman.

This little book, published at a price which places it within the reach of a large public, describes very plainly in popular language the evolution of the best modern burners of Sugg, of Bray, and of Siemens, from the original "cock-spur burner" of Murdock, and Accum's "tube with a simple orifice, at which the gas issues in a stream, and if once lighted will continue to burn with the most steady and regular light imaginable, as long as the gas is supplied." The illustrations are all that can be desired.

Owen Merriman has taken pains to insist on the two great *desiderata* of gas-burners—high temperature and low temperature, but we think he has gone too far in attempting to give a popular "theory of luminous combus-

[1] "Gas-Burners, Old and New." By Owen Merriman. (London: Walter King, 1884.)

tion." We are told that "the various gases which constitute ordinary coal-gas do not all burn together in the flame; . . . thus hydrogen is the first to burn, taking fire readily as soon as it issues from the burner, while the combustion of heavy hydrocarbons does not commence until they enter the hotter portions of the flame." Again Owen Merriman says: "the amount of light developed by any coal-gas flame is *directly proportional* to the degree of intensity to which the temperature of the carbon particles is raised." The italics are ours. In a note on page 23 there is some confusion as to the effect of the admission of air into a Bunsen burner. "A continuous wind blowing upon the flame destroys its luminosity altogether, because the heat intensity of the flame is *lowered below the temperature necessary to decompose the hydrocarbons*: consequently these latter burn without the preliminary separation of carbon, and a non-luminous flame is produced—exactly as in the Bunsen burner." The reader would gather from this that the flame of a Bunsen was colder than an ordinary flame, and by the same argument the blast of a blow-pipe would render a gas-flame colder instead of hotter. And again on page 43 a similar mistake is made when we are told that a too long flame is bad because the gas is "brought too early into intimate contact with air, and so oxidised, or fully consumed, *before its carbon has been raised to the temperature necessary to enable it to give out light.*" We point out these few blemishes in the hope that the author may correct them in a future edition of the work, to which we wish a hearty success.

BIRDS'-NEST SOUP

IT is scarcely probable that the famous birds'-nest soup which Chinese cooks at the Health Exhibition offer to favoured visitors will ever become a popular dish in England. The tasteless, gelatinous compound is not suited to our palates. Perhaps this is not to be regretted, as the supply of material for this mysterious compound is far from being inexhaustible. There appears to be only one place in the world where it can be obtained in any quantity, and this has recently been visited by Mr. Pryer, a naturalist of Yokohama, who communicates his observations to the *Japan Gazette*, an English journal published in that settlement. Leaving Elopura, the infant capital of the infant colony of British North Borneo, in March last, Mr. Pryer ascended for some thirty miles the Sapugaya River, which flows into Sandakan Bay, on which the town is built. Passing through the mangrove and nipa swamps which line the banks, he arrived at noon on the second day at his destination—the celebrated birds'-nest caves of Gomanton. These caves, which are two in number, called by the natives the Black and the White Caves, are situated in a limestone cliff 900 feet in height, which the traveller came on quite suddenly in the centre of the forest. The porch, Mr. Pryer writes, is rather over 100 feet wide by 250 high, and the roof slopes up for 110 feet more, so that the height of this magnificent natural cathedral is 360 feet. The interior of the Black Cave is well lighted, as there is a large circular hole in the roof on the right, and a smaller one on the left, forming two aisles. The walls and roof are rugged, and beautifully coloured, shading from black to brown, gray, dark yellow, red, and green. The nests of the bats and swifts were seen hanging in clusters from the sides and roof, and here and there in seemingly the most inaccessible places were the rattan stages, ladders, and ropes of the nest-gatherers. These latter reached their perilous heights by means of many smaller caves in the cliff above. The White Cave is 400 feet higher up than the Black Cave, and at the entrance to this the nest-gatherers live under a guard of the North Borneo Company's soldiers. After some examination Mr. Pryer was able to discover the material which forms these mysterious nests, and from which they derive the qualities which render them so highly prized in China. They are made from a soft fungoid growth that incrusts the limestone in all damp situations; it grows about an inch thick, outside dark brown, but inside white. The birds make the black nests from the outside layer, and the best quality of white nests are, of course, from the inside. It is taken by the bird in its mouth, and drawn out in a filament backwards and forwards like a caterpillar weaving its cocoon. At nightfall takes place what the natives style with much justice the most wonderful sight in all Borneo, and it might be added, one of the most wonderful sights in the world—viz. the return of the swifts to their nests, and the departure of the bats for the night. About that time a rushing sound was heard, and peering over the abyss into the Black Cave Mr. Pryer saw columns of bats wheeling round and round the sides in regular order; soon they began to circle up, rising into the air in a corkscrew flight. Having reached a certain height, a detachment would break off and fly away rapidly. He counted nineteen flocks go off like this, each flock consisting of many thousands, and then they commenced to pour away in a continuous stream until it was too dark to see them any longer. Soon after the bats emerged from their cave, the swifts began to return to theirs, first in tens, then in hundreds, and at last they too streamed in continuously, and when the traveller went to sleep at midnight they were still flying in in undiminished numbers. Rising before daylight the following morning, Mr. Pryer witnessed a reversal of the proceedings of the previous night, the swifts going out and the bats coming home. The latter, he says, literally rained into their chasm for two hours after sunrise; looking up to the bright sky, numbers of small specks appear, flash down perpendicularly with great rapidity, and disappear into the darkness. From specimens of the bat which were secured, they were found to be all of one species, the caudal membrane extending only half down the tail, which is free for an inch and a half, giving the animal, when the wings are folded up, very much the appearance of a mouse. The wings are very long and narrow, and it flies with great speed. Two species of birds of prey—one a kite, the other a hawk—the *Haliaster indus* and the *Machærhamphus alcinus*, prey on the bats and swifts when swarming into and out of the caves. A detailed examination of the latter was rendered disagreeable by enormous quantities of guano, the deposit of centuries. Its depth is not known, but a long spear does not touch the bottom when thrust in to the hilt. All the roof of the dark parts of the cave was occupied by birds who keep up an intermittent twittering, sounding, from the immense number of them, like the surf beating on a rocky shore. Near the centre of the largest cave the explorer was shown a small beam of light from a funnel at the top of the rock, exactly 696 feet above his head. The nests are gathered from these enormous elevations by means of flexible rattan ladders and stages. On these two men take their station; one carries a light four-pronged spear about 15 feet long, and just below the prongs a lighted candle is fixed. Holding on to the ladder with one hand, the spear is managed with the other, and the nest transfixed, a slight push detaching it from the rock. The spear is then withdrawn until the head is within reach of the second man, who takes the nest off the prongs and puts it in a pouch carried at the waist. According to statements made by the headman of the place, the annual value of the nests taken varies from five to six thousand pounds sterling. This, it is to be presumed, means the value on the spot; their value on reaching China must be far higher. The caves have been worked for seven generations without any apparent diminution, although three crops are gathered in the year. Notwithstanding the dangerous nature of their occupation—for even samphire-gatherers work in the open—accidents are very rare amongst the natives employed in

collecting the nests. There is an almost inexhaustible supply of guano in the caves, and the number of bats and swifts in them is so enormous that if they are undisturbed a regular quantity may be taken out yearly. Should the visitor to the Health Exhibition who obtains some of this far-famed and mysterious soup have little relish for it, as is not unlikely, he will at any rate have the satisfaction of knowing that he has before him a dish the principal ingredient of which was formed by the little swifts and bats which inhabit the Gomanton Caves in the centre of the magnificent tropical forests of North Borneo. There is probably no other article of food in the Health Exhibition, or in all Europe, more extraordinary in the mode of production, or in the method and circumstances under which it is obtained.

ON THE EVOLUTION OF FORMS OF ORNAMENT[1]

II.

THE leaf in Dracunculus has a very peculiar shape: it consists of a number of lobes which are disposed upon a stalk which is more or less forked (tends more or less to dichotomise). If you call to your minds some of the Pompeian wall decorations, you will perceive that similar forms occur there in all possible variations. Stems

Fig. 12.

are regularly seen in decorations that run perpendicularly, surrounded by leaves of this description. Before this, these suggested the idea of a misunderstood (or very conventional) perspective representation of a circular flower. Now the form also occurs in this fashion, and thus negatives the idea of a perspective representation of a closed flower. It is out of this form in combination with the flower-form that the series of patterns was developed which we have become acquainted with in Roman art, especially in the ornament of Titus's Thermæ and in the Renaissance period in Raphael's work. [The lecturer here explained a series of illustrations of the ornaments referred to (Figs. 12, 13, 14).]

[1] From a paper by Prof. Jacobsthal in the *Transactions* of the Archæological Society of Berlin. Continued from p. 251.

The attempt to determine the course of the first group of forms has been to a certain extent successful, but we meet greater difficulties in the study of the second.

It is difficult to obtain a firm basis on which to conduct our investigations from the historical or geographical point of view into this form of art, which was introduced into the West by Arabico-Moorish culture, and which has since been further developed here. There is only one method open to us in the determination of the form, which is to pass gradually from the richly developed and strongly differentiated forms to the smaller and simpler

Fig. 13.

ones, even if these latter should have appeared contemporaneously or even later than the former. Here we have again to refer to the fact that has already been mentioned, to wit, that Oriental art remained stationary throughout long periods of time. In point of fact, the simpler forms are invariably characterised by a nearer and nearer approach to the more ancient patterns and also to the natural flower-forms of the Araceæ. We find the spathe, again, sometimes drawn like an Acanthus leaf, more often, however, bulged out, coming to be more and more of a mere outline figure, and becoming converted into a sort of background; then the spadix, generally conical in

Fig. 14.

shape, sometimes, however, altogether replaced by a perfect thistle, at other times again by a pomegranate. Anberville in his magnificent work "L'Ornement des Tissus," is astonished to find the term pomegranate-pattern almost confined to these forms, since their central part is generally formed of a thistle-form. As far as I can discover in the literature that is at my disposal, this question has not had any particular attention devoted to it except in the large work upon Ottoman architecture, published in Constantinople under the patronage of Edhem Pasha. The pomegranate that has served as the original of the pattern in question is in this work surrounded with leaves

gives some sort of an approach to the pattern. : are important suggestions in the book as to the employment of melon-forms.) Whoever has picked the fruit from the tender twigs of the pomegranate-tree, which are close set with small altered leaves, will never dream of attributing the derivation of the thorny leaves that

FIG. 15.

appear in the pattern to pomegranate-leaves at any stage of their development.

It does not require much penetration to see that the outline of the whole form corresponds to the spathe of the Araceæ, even although in later times the jagged contour is all that has remained of it, and it appears to have been provided with ornamental forms quite independently of

FIG. 16.

the rest of the pattern. The inner thistle-form cannot be derived from the common thistle, because the surrounding leaves negative any such idea. The artichoke theory also has not enough in its favour, although the artichoke, as well as the thistle, was probably at a later time directly pressed into service. Prof. Ascherson first called my attention to the extremely anciently cultivated plant, the

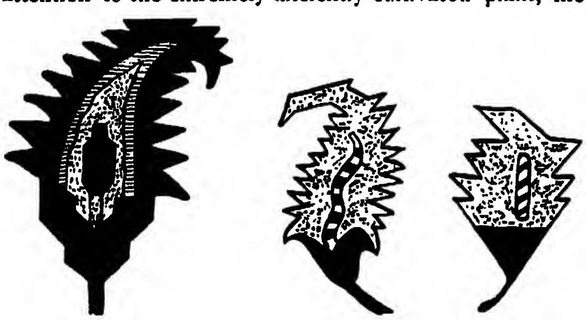

FIG. 17. FIG. 18. FIG. 19.

Safflor (*Carthamus tinctorius*, Fig. 15), a thistle plant whose flowers were employed by the ancients as a dye. Some drawings and dried specimens, as well as the literature of the subject, first gave me a hope to find that this plant was the archetype of this ornament, a hope that was borne out by the study of the actual plant, although I was unable to grow it to any great perfection.

In the days of the Egyptian King Sargo (according to Ascherson and Schweinfurth) this plant was already well known as a plant of cultivation; in a wild state it is not known (De Candolle, "Originel des Plantes cultivées"). In Asia its cultivation stretches to Japan. Semper cites a passage from an Indian drama to the effect that over the doorway there was stretched an arch of ivory, and about it were bannerets on which wild safran (*Saflor*) was painted.

The importance of the plant as a dye began steadily to decrease, and it has now ceased to have any value as such in the face of the introduction of newer colouring matters (a question that was treated of in a paper read a short time ago by Dr. Reimann before this Society). Perhaps its only use nowadays is in the preparation of rouge (*rouge végétale*).

But at a time when dyeing, spinning, and weaving

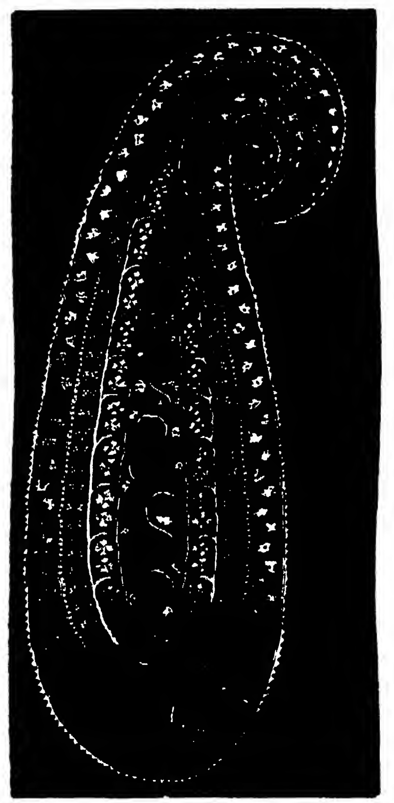

FIG. 20.

were, if not in the one hand, yet at any rate intimately connected with one another in the narrow circle of a home industry, the appearance of this beautiful gold-yellow plant, heaped up in large masses, would be very likely to suggest its immortalisation in textile art, because the drawing is very faithful to nature in regard to the thorny involucre. Drawings from nature of the plant in the old botanical works of the sixteenth and seventeenth centuries look very like ornamental patterns. Now after the general form had been introduced, pomegranates or other fruits—for instance, pine-apples—were introduced within the nest of leaves.

Into the detailed study of the intricacies of this subject I cannot here enter; the East-Asian influences are not to be neglected, which had probably even in early times an effect upon the form that was assumed, and have fused the correct style of compound flowers for flat ornament with the above-mentioned forms, so as to produce peculiar

patterns; we meet them often in the so-called Persian textures and flat ornaments (Fig. 16).

We now come to the third group of forms—the so-called Cashmere pattern, or Indian palmetta. The developed forms which, when they have attained their highest development, often show us outlines that are merely fanciful, and represent quite a bouquet of flowers leaning over to one side, and springing from a vessel (the whole corresponding to the Roman form with the vessel), must be thrown to one side, while we follow up the simpler forms, because in this case also we have no information as to either the where or the when the forms originated. (Figs. 17, 18, 19.)

Here again we are struck by resemblances to the forms that were the subjects of our previous study, we even come across direct transitional forms, which differ from the others only by the lateral curve of the apex of the leaf; sometimes it is the central part, the spadix, that is bent outwards, and the very details show a striking agreement with the structure of the Aroid inflorescence, so much so that one might regard them as actually copied from them.

This form of ornament has been introduced into Europe since the French expedition to Egypt, owing to the importation of genuine Cashmere shawls. (When it cropped up in isolated forms, as in Venice in the fifteenth century, it appears not to have exerted any influence; its introduction is perhaps rather to be attributed to calico-printing.) Soon afterwards the European shawl-manufacture, which is still in a flourishing state, was introduced. Falcot informs us that designs of a celebrated French artist, Couder, for shawl-patterns, a subject that he studied in India itself, were exported back to that country and used there (Fig. 20).

In these shawl-patterns the original simple form meets us in a highly developed, magnificent, and splendidly coloured differentiation and elaboration. This we can have no scruples in ranking along with the mediæval plane-patterns, which we have referred to above, among the highest achievements of decorative art.

It is evident that it, at any rate in this high stage of development, resisted fusion with Western forms of art. It is all the more incumbent upon us to investigate the laws of its existence, in order to make it less alien to us, or perhaps to assimilate it to ourselves by attaining to an understanding of those laws. A great step has been made when criticism has, by a more painstaking study, put itself into a position to characterise as worthless, ignorantly imitated, or even original, miscreations such as are eternally cropping up. If we look at our modern manufactures immediately after studying patterns which enchant us with their classical repose, or after it such others as captivate the eye by their beautiful colouring, or the elaborative working out of their details, we recognise that the beautifully-balanced form is often cut up, choked over with others, or mangled (the flower springing upside down from the leaves), the whole being traversed at random by spirals, which are utterly foreign to the spirit of such a style, and all this at the caprice of uncultured boorish designers. Once we see that the original of the form was a plant, we shall ever in the developed artistic form cling, in a general way at least, to the laws of its organisation, and we shall at any rate be in a position to avoid violent incongruities.

I had resort, a few years ago, to the young botanist Ruhmer, assistant at the Botanical Museum at Schöneberg, who has unfortunately since died of some chest-disease, in order to get some sort of a groundwork for direct investigations. I asked him to look up the literature of the subject, with respect to the employment of the Indian Araceæ for domestic uses or in medicine. A detailed work on the subject was produced, and establishes that, quite irrespective of species of Alocasia and Colocasia that have been referred to, a large number of Araceæ were employed for all sorts of domestic purposes. Scindapsus, which was used as a medicine, has actually retained a Sanscrit name, "vustiva." I cannot here go further into the details of this investigation, but must remark that even the incomplete and imperfect drawings of these plants, which, owing to the difficulty of preserving them, are so difficult to collect through travellers, exhibit such a wealth of shape, that it is quite natural that Indian and Persian flower-loving artists should be quite taken with them and employ them enthusiastically in decorative art. Let me also mention that Haeckel, in his "Letters of an Indian Traveller," very often bears witness to the effect of the Araceæ upon the general appearance of the vegetation, both in the full and enormous development of species of Caladia and in the species of Pothos which form such impenetrable mazes of interlooping stems.

In conclusion, allow me to remark that the results of my investigation, of which but a succinct account has been given here, negative certain derivations, which have been believed in, though they have never been proved; such as that of the form I have last discussed from the Assyrian palmetta, or from a cypress bent down by the wind. To say the least the laws of formation here laid down have a more intimate connection with the forms, as they have come down to us, and give us a better handle for future use and development. The object of the investigation was, in general words, to prepare for an explanation of the questions raised, and even if the results had turned out other than they have, it would have sufficed me to have given an impulse to labours which will testify to the truth of the dead master's words:—

"Was Du ererbt von deinen Vätern hast,
Erwirb es, um es zu besitzen."

NOTES

The death is announced, at the age of seventy-four years, of Prof. Lepsius, the celebrated Egyptologist.

The conference and jury work at the Health Exhibition is now in full swing, and we are glad to note that, with regard to the Conference, all the societies and organisations that have to deal with subjects akin to health or education are taking up the matter very warmly, so that the executive of the Exhibition has the advice and opinion of many experts. The recent opening of the Educational Section by the Prince of Wales, to which we have already referred, has recently drawn more attention to the *mens sana*, the *corpus sanum* having up to the present moment been alone regarded. From the first we consider that the matter of education has been placed altogether in far too secondary a position, and if a little more trouble had been taken by those who are responsible for the Exhibition, the educational exhibits might have been as extensive and as important as those regarding health. That is the more to be regretted because so much is being said about education nowadays, especially technical education, by those who know very often very little of what is really wanted, and of what true technical education really means. The members of the various juries are working with a will, and from what we learn we do not think it probable that the objections made to some of the awards last year will be renewed this. The opportunity which has been afforded to the exhibitors of practically nominating a considerable number of jurymen is a measure well adapted to allow the thing to work smoothly. One of the great difficulties encountered by the jurymen has been the hurried way in which the Exhibition itself has been put together and catalogued. We have for too great an extent a succession of shops containing various articles, instead of a complete separation of the various articles among their several classes. This of course gives great trouble to all concerned, and is an administrative blunder which should not be allowed to be repeated.

We are glad to be able to announce that H.R.H. the Prince of Wales has become Patron of the Marine Biological Association, and has contributed a handsome donation to its funds. The following is now the full list of Officers and Council as definitely elected by the Association, at its meeting on June 17:—Patron, H.R.H. the Prince of Wales, K.G. President, Prof. Huxley (President of the Royal Society). Vice-Presidents: The Duke of Argyll, K.G., the Duke of Sutherland, K.G., the Marquis of Hamilton, the Earl of Dalhousie, K.T., Lord Walsingham (Trustee of the British Museum of Natural History), Edward Birkbeck, M.P. (Chairman of the Executive Committee of the International Fisheries Exhibition), George Busk, F.R.S., W. B. Carpenter, C.B., M.D., F.R.S., W. H. Flower (Director of the British Museum of Natural History), J. Gwyn Jeffreys, F.R.S., Sir John Lubbock, Bart., M.P. (President of the Linnean Society). Council: Prof. Moseley, F.R.S. (Oxford), Chairman, Prof. Jeffrey Bell, F.Z.S. (British Museum), W. S. Caine, M.P., W. T. Thiselton Dyer, C.M.G. F.R.S. (Royal Gardens, Kew), John Evans, D.C.L. (Treasurer Royal Society), A. C. L. G. Günther, F.R.S. (British Museum), Prof. Herdman (Liverpool), E. W. H. Holdsworth, Prof. McIntosh (St. Andrew's), Prof. Milnes Marshall (Manchester), Sir Philip Cunliffe Owen, K.C.M.G., C.B., G. J. Romanes, F.R.S. (Sec. Linn. Soc.), P. L. Sclater, F.R.S. (Sec. Zool. Soc.), Adam Sedgwick (Cambridge). Hon. Treasurer, Frank Crisp, (V.P. and Treas. Linn. Soc.), 6, Old Jewry, E.C. Hon. Secretary, Prof. E. Ray Lankester, F.R.S., 11, Wellington Mansions, North Bank, N.W.

We regret to learn of the death of the venerable Abbé Moigno at the age of eighty-one years. The name of the Abbé has been long known in connection with French science, and more especially as the founder, and till quite recently the editor, of *Les Mondes*.

It is proposed to hold a special American Exhibition in London in May 1886, at which the products, manufactures, and varied phases of life in the United States will be represented.

By a decree dated Ems, July 4, the Emperor conveys his thanks to Dr. Auwers, the celebrated astronomer who so successfully superintended the German preparations for observing the transits of Venus in 1874 and 1882. The Emperor further expresses his thanks for the assistance so hospitably rendered to the German scientific expeditions, not only by Germans living abroad, but also by many persons belonging to other nationalities.

Biologists attending the Montreal meeting of the British Association will be pleased to hear that Prof. Asa Gray has promised to be present and to read a paper in Section D "On some characteristic features of the Botany of North America," with the special view of aiding botanists and members of the Section generally in their appreciation of the flora.

It is announced from Montreal that a large number of the members of the British Association visiting Canada next month have already been "placed" in private houses in the city. The matter continues to be very heartily taken up in the towns of the Dominion, and there is every probability of a warm welcome being extended to the members. Considerable amusement has been caused in Montreal by some of the letters received by the Montreal Committee of the British Association from those members on this side of the Atlantic desiring information regarding Canada. The climate of the country is evidently a subject upon which there is much misconception among members. The queries on this point are most exacting, while a quite unwarranted dread of mosquitoes is held by not a few members. It is satisfactory to learn that a circular is now in course of preparation that will answer most of the queries received by letter, and that on the completion of the labours of the Private Hospitality Committee a directory of the visitors will be published.

Prof. R. S. Ball has accepted an invitation from the Lowell Institute, Boston, United States, to give a course of six lectures on "Chapters in Modern Astronomy" next October.

The Society of Chemical Industry held their annual meeting in Newcastle last week. Dr. Perkin, F.R.S., was elected President for the next year.

Under the auspices of the Royal Geographical Society, Mr. E. C. Rye has done a most useful service to students by compiling a New Guinea Bibliography. It will be appended to Mr. C. R. Markham's paper on New Guinea, to be issued in No. 2, vol. i. of the Society's Supplementary Papers. Mr. Rye's Bibliography covers over fifty pages, and contains considerably over a thousand entries. It is evidently the result of immense labour and research, and is practically exhaustive. It includes not merely geography proper, but every aspect of the country; the references to natural history are specially copious, and include not only books but papers and notes in periodical publications of all kinds. The references are of the most precise character, and the whole is worthy of the editor of the *Zoological Record*.

It may interest many of our readers—especially those who would like to add to the pleasure of a tour by a little photography—to know that the London Stereoscopic Company give gratuitous private lessons to amateurs who purchase their apparatus from the Company. We have no doubt this will solve a prime difficulty in the case of many who are ambitious to be able to photograph on their own account, but who do not know how to take the first step.

Notwithstanding the troubles that have surrounded Madagascar for the last year or two, the scientific activity of the missionaries of the London Missionary Society has not abated, and the native printing press has not been idle. We have just received from Antananarivo two numbers of the *Antananarivo Annual and Madagascar Magazine*, edited by the Rev. R. Baron, containing numerous papers of varied scientific interest. The following are those of most importance:—The Sakalava (No. 2), by the Rev. A. Walin; Notes on four species of Lemur and on the Aye-Aye, by Mr. G. A. Shaw; Customs connected with death and burial in Malagasy, by the Rev. S. E. Jorgensen; Resemblance between Malagasy words and customs and those of Western Polynesia, by the Rev. R. S. Codrington. In No. 7 for 1883 we have—The race elements of the Malagasy, by the Rev. L. Dahle; the Sakalava (No. 3), by the Rev. A. Walin; Volcanoes in Eastern Imerina, by the Editor; Malagasy "Fady" (Tabu), by Mr. H. E. Standing; Genera of Malagasy plants, by the Editor; Relics of sign and gesture language among the Malagasy, by the Rev. J. Sibree; and various natural history and meteorological notes.

Dr. Regel, the Russian traveller, who recently arrived in Merv, intends proceeding along the northern mountain slopes of Afghanistan and the Amu Daria to Pamir. This journey will conclude the doctor's explorations in Central Asia.

The Milan Society for the Commercial Exploration of Africa has organised a circumnavigation of Africa, with a view of affording the pupils of the High School of Commerce, and others, an opportunity of becoming acquainted with likely markets for Italian products. The steamer will leave Genoa on September 1, and the whole voyage will occupy four months. A professor is to lecture during the voyage on the commercial geography of Africa.

The first mail from Kadiak Island received this season, *Science* states, has arrived at San Francisco, bringing dates to May 2. According to the correspondent of the *Bulletin*, the account of the eruption of the volcano on Augustine Island, Cook's Inlet, sent by the last advices of 1883, was much exaggerated. The island "was not split in two, and no new island was formed

but the west side of the summit has fallen in, forming a new crater, while the whole island has risen to such an extent as to fill up the only bay or boat harbour, and to extend the reefs, or sea-otter rocks, running out from the island in various directions." The hunting-party feared to be lost has arrived safely in Kadiak. No tidal waves were observed on the west shore of Cook's Inlet or on Kadiak Island. The winter had been very mild, the mercury not having fallen below 10° F.; and spring began in March, wild flowers being in bloom in the latter part of April.

THE educational statistics of Japan for the past year show that the number of common schools throughout the country is 29,081, being an increase of 339 as compared with the preceding year, while the number of scholars is 3,004,137, an increase of 396,960, and the number of teachers is 84,765, being an increase of 8147.

THE Swedish Government have granted a sum of 850*l.* for the establishment of five additional so-called "chemical" stations, in order to benefit the agriculturist with scientific advice as to the crops, their diseases, &c.

THE sixth Davis Lecture of the Zoological Society of London was given in the Lecture-Room in their Gardens in Regent's Park, on Thursday, the 10th inst., by Mr. Henry Seebohm. The subject was that of "Birds' Nests," and consisted of an account of the breeding of birds on the Fern Islands off the coast of Northumberland, on the Derbyshire Moors, and in the valley of the Lower Danube. The lecturer pointed out that, so far as regards the means which birds take for the protection of their eggs, they may be classified in five groups—(1) those which rely upon the concealed position of the nest, such as the kingfishers, bee-eaters, pigeons, &c.; (2) those which rely upon the inaccessible position of the nest, such as guillemots, herons, &c.; (3) those which rely upon the protective colour of the eggs, such as sandpipers, terns, &c.; (4) those which rely upon the protective colour of the sitting hen, such as the blackbird, game birds, &c.; (5) those which rely upon their own ability, either singly, in pairs, or in colonies, to defend their eggs, such as cormorants, birds of prey, &c. Mr. Seebohm laid great stress upon the much greater interest to be found in the study of the life and habits of birds than in the investigation of the form and colour of their feathers or the peculiarities of their anatomy.

UNDER the auspices of the East India Association, a meeting of naturalists, planters, sportsmen, and others interested in the affairs of India, was held on Friday, July 11, at the rooms of the Zoological Society, under the presidency of Prof. Flower, LL.D., F.R.S. (Director of the British Museum Natural History Department, and President of the Zoological Society), for the purpose of urging the necessity of Government measures for the preservation of wild birds in India. The principal address was delivered by Mr. Robt. H. Elliot, sometime planter of Mysore, and a well-known writer upon Indian topics. He pointed out that every civilised Government with the exception of that of India has recognised the value of birds as insect-eaters, and has adopted measures for their preservation; and that the absence of legislation forebodes, where it has not yet presented, serious results to planters and agriculturists. As the most convenient season for the destruction of birds is during the fine weather that succeeds the heavy rains of the monsoons, and as this season is also the breeding time, the destruction of insect-eating birds proceeds at such a rate as must soon lead to almost absolute extermination unless preservative measures are speedily adopted. There was a general agreement at the meeting that legislation on the subject is imperatively required; and it was resolved that a representation to that effect should be addressed to the Government of India.

MR. J. H. ANGAS, who has already founded an engineering scholarship of the annual value of 200*l.* in the Adelaide University, has signified his intention of endowing a Chair of Chemistry. For this purpose Mr. Angas is prepared to give the sum of 6000*l.*, and to pay an annual sum of 350*l.* until he pays over the capital sum. A letter to this effect from Mr. J. H. Angas was recently read by the Chancellor at a special meeting of the Council. The Council resolved to accept the gift, and authorised the Chancellor to write and thank Mr. Angas for his continued munificence to the University.

PROF. MILNE of Tokio, Japan, writes to us:—"A short time ago I described a pair of conical pendulum seismographs. Each seismograph consisted of a heavy mass suspended by a string, &c. A local paper describing this innocently gave to the world an account of a pair of 'comical pendulums.' Each 'comical' pendulum consisted of a heavy 'man' suspended at the end of a string, &c. These errors, which were repeated throughout the article, did so much to popularise the instrument that their correction was neglected."

A RECENT number of *L'Exploration* contains an article by the Chancelier of the French Consulate at Hanoi, M. Aumoitte, which possesses special interest at the present time. It is the record of a journey from Hanoi through Bacninh to Langson on the Chinese frontier, thus following the same route as the French troops have done in their recent operations in Tonquin. From Hanoi to the meeting of the provinces of Bacninh and Langson, the country is described as populous and fertile, but on entering the latter district it becomes mountainous, with bad roads, and almost depopulated by the brigand hordes which have infested this borderland. Almost everywhere the water is bad, and fever rife even amongst the natives. Nowhere is this the case more than at Bacle, where the French forces are now hurrying up to retrieve the recent reverse at Langson. The country around Langson is described as healthy, it is rich in rice and cotton, but the trade here, as all along the valley of the Red River, is in the hands of the Chinese. When the French occupy this region, and when the recent treaty is carried out, we may expect a vast addition to our scanty knowledge of the geography of this little visited region.

FROM a paper contributed by the veteran scholar, Dr. Edkins, to a recent number of the *Chinese Recorder*, it appears that about B.C. 2200 the Chinese possessed a knowledge of the art of writing, a year of 366 days with an intercalary month, the astrolabe, the zodiac, the cycle of sixty, of twelve musical reeds forming a gamut, which also constituted the basis of a denary metrology for measures of length, weight, and capacity, divination, and a feudal system. In B.C. 1130 they were acquainted with the clepsydra and with the gamut of five musical notes. "Human knowledge was systematised in a scheme of numerical categories in which the five elements played a special part." About B.C. 550 the silk trade sprang into existence, the stars were classified, foreign names of unknown origin were introduced for the purpose of applying the cycle of sixty-two years. About B.C. 140 Chinese travellers visited Afghanistan, India, Bactria, &c. The cycle of Calippus was introduced into Chinese astronomy, and geographical knowledge concerning western nations was acquired. In the first two centuries of our era trade became more extended by sea; paper-making and the manufacture of ink were introduced from Europe, the Babylonian cosmogony became the main element of the Taoist cosmogony, and the gamut of five was increased to seven notes.

THE last volume (ii.) of the *Revue d'Ethnographie* contains, among others, articles by M. Bertrand on the Troglodytes, the introduction of metals into the West, and the great routes of migration and commerce in the earliest historical period; by M. Charnay, on the ruins in Yucatan; by M. Deniker, on the Giliaks; by Dr. Martin, on the cranial malformation of the

Chinese; by M. Ujfalvy, on the Aryans north and south of the Hindoo Koosh; and by Baron Vaux, on the Kanakas of New Caledonia.

THE additions to the Zoological Society's Gardens during the past week include two Quebec Marmots (*Arctomys monax* ♂ ♀) from North America, presented by Mr. N. Stainfield; a Prairie Wolf (*Canis latrans* ♂) from North America, presented by Mr. R. Payze; three Suricates (*Suricata tetradactyla*) from South Africa, presented by Mr. W. R. Dobbin; two Red-beaked Weaver Birds (*Quelea sanguinirostris* ♂ ♀) from West Africa, presented by Mrs. Nettleship; two Swift Parrakeets (*Lathamus discolor* ♂ ♀) from Tasmania, presented by Mr. J. Abrahams; four Common Vipers (*Vipera berus*), British, presented by Mr. Walter E. Blaker; two Smooth Snakes (*Coronella lævis*), British, presented by the Rev. Charles Harris; two Red Kangaroos (*Macropus rufus* ♂ ♀), a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, deposited; four Beautiful Finches (*Estrelda bella* ♂ ♂ ♀ ♀) from Australia, a Lanner Falcon (*Falco lanarius*), captured at sea, purchased; a Hybrid Luhdorf's Deer (between *Cervus luehdorfi* ♂ and *C. canadensis* ♀), a Hybrid Mesopotamian Deer (between *Dama mesopotamica* ♂ and *D. vulgaris* ♀), a Red Deer (*Cervus elaphus* ♀), four Australian Wild Ducks (*Anas superciliosa*), a Mandarin Duck (*Æx galericulata*), bred in the Gardens.

ZOOLOGICAL NOMENCLATURE[1]

II.

DR. COUES said that he was much gratified at the interest shown in the subject of zoological nomenclature, and indorsed the words of the Chairman that names were of the greatest possible consequence. Nomenclature was a necessary evil, and the point was always to employ that method of naming objects which should most clearly reflect not only the characters of the objects themselves, but our ideas respecting those characters and the view we take of them. As to what constitutes a species, there had been an absolute revolution in the definition of a species since the time of Linnæus, the opinion having been long held that every species was a distinct and individual creation. But that idea had passed out of existence in the minds of most natural historians of the present day, who accepted a general theory of the evolution of species by a gradual modification. That being the case, it was idle to inquire "What is a species?" no such thing existing any more than a genus; and so intimately related were all forms of animal and vegetable life that, if they were all before us, no naming would be possible, for each would be found to be connected completely with another; therefore the possibility of naming any species was, as it were, the gauge and test of our ignorance. Having thus touched very briefly upon the subject of missing links, which alone enable us to name objects which still exist, Dr. Coues proceeded to inquire, "What of so-called species the connecting links between which are still before our eyes?" In illustration of this he would cite some instances of connecting links which exist between certain forms. He then referred to the case of one of the best-known Woodpeckers in North America (*Picus villosus*), and discussed its climatal and geographical variation. He was of opinion that all these geographical races were indistinctly separable forms, and he would indicate them by trinomial names, proceeding upon the definite principle of geographical variation according to conditions of environment, meaning by this all the external influences which modify the plastic organism. Moisture, the humidity of the atmosphere, appeared to have the greatest effect, particularly in regard to colour. Latitude, with its varying degrees of heat, determined size more than any other influence. As a matter of fact this condition of things was found to occur, and the question was, How should we recognise it in our language? Specification had ceased to be of use, and the question was whether the system in favour in America was sufficient or insufficient to meet the case. On these points he would be glad to hear opinions; and in concluding he would read a paragraph from the new edition of the "Key to North American Birds," giving formally the rule for the employment of trinomials as now in use by American ornithologists and many other zoologists of the United States. This rule is as follows:—

"No infallible rule can be laid down for determining what shall be held to be a species, what a con-species, sub-species, or variety. It is a matter of tact and experience, like the appreciation of the value of any other group in zoology. There is, however, a convention upon the subject, which the present workers in ornithology in this country (America) find available—at any rate, we have no better rule to go by. We treat as 'specific' any form, however little different from the next, that we do not know or believe to intergrade with that next one;—between which and the next one no intermediate equivocal specimens are forthcoming, and none, consequently, are supposed to exist. This is to imply that the differentiation is accomplished, the links are lost, and the characters actually become 'specific.' We treat as varietal of each other any forms, however different in their extreme manifestation, which we know to intergrade, having the intermediate specimens before us, or which we believe with any good reason do intergrade. If the links still exist, the differentiation is still incomplete, and the characters are not specific, but only varietal, in the literal sense of these terms. In the latter case, the oldest name is retained as the specific one, and to it is appended the varietal designation."[1]

Dr. Günther, F.R.S., said that during the whole of this discussion it appeared to him that this new movement was in fact a reaction. It had always appeared to him that ornithologists went too far in attaching to the slightest modification of colour the rank of a species; and when he looked over the list of species of a genus well known to him, he found there a number of different forms distinguished for very different reasons, and could not help being struck by the great diversity of value which was attached to the distinctive characters of these various forms. There was nothing to show that there was any system in distinguishing and naming the species of birds. He looked with favour on the method proposed by Dr. Coues and his compatriots. It was a system he had himself employed occasionally in his systematic writings since 1866, and Dr. Coues would find that in some cases he had adopted it pure and simple. He (Dr. Günther) had been disappointed in looking over the new edition of Dr. Coues' "Key to North American Birds," for he found there that Dr. Coues adopted trinomials in some cases and binomials in others. He maintained that logically one ought to adopt the trinomial nomenclature for all other forms, and keep the binomial only for that category in which these varieties may be contained. If Dr. Coues and those who were with him adopted that system, he for one would gladly employ it in all those cases in which the geographical range of certain forms is clearly ascertained.

Dr. Sclater, F.R.S., would remind Dr. Coues that this mode of designating the forms of animal life was by no means a new one, as might be seen on reference to Schlegel's "Revue Critique," published in 1844. He thought the only difficulty lay in the extent to which it was likely to be carried out. Dr. Coues, in his preface to the new "Key to the Birds of America" had hinted at this difficulty. If too much stress were laid upon the value of trinomialism we should open the flood-gates to an avalanche of new names by naturalists who have not taken enough trouble to investigate the matter under consideration. The time had now come when it would be advisable to a certain extent to use trinomials. He could not at all agree with Dr. Coues when he said that no such thing as species exists, for forms were known which had all the characters of well-marked species. It was only in cases where faunæ had been fully worked out that trinomial names would come into use, and for such forms he was quite prepared to adopt the system.

Mr. Blanford, F.R.S., said that he would add one word to the discussion, as nobody else had taken up the one or two points which might be advanced in opposition to the proposed system. He thought the movement an unfortunate one, for the reason that it would certainly have the effect of rendering nomenclature in general less certain than it was before. An equation containing three variables was much more complicated than one in which there were only two, and when one had three names any one of which was liable to be changed to suit personal views the fixture of nomenclature would be even further off than it is now. Then the case of ornithology was not nearly, in point of fact, so complicated as some other classes, as, for instance, in the Mollusca. Trinomial nomenclature had been proposed to,

[1] Continued from p. 259.

[1] A more formal and elaborate presentation of Dr. Coues' views may be found in the *Zoologist* for July, 1884, p. 241, being the verbatim report of the address delivered before the National Academy of Sciences at Washington U.S.A., in April last.—ED.

but almost universally rejected by, a meeting of geologists. He did not consider that the time had arrived for any innovation, and thought it desirable first to agree upon strict rules of zoological nomenclature.

Prof. Bell agreed with Mr. Blanford that the method would not be universally applicable. How could it be applied for instance to cases where varieties were found living with one another, as was often the case with littoral forms with free-swimming embryos?

Mr. W. F. Kirby said that it was necessary to distinguish sub-species and varieties at times, and there seemed to be only two courses open to us, either to retain the binomial nomenclature, and to treat sub species, so far as nomenclature was concerned, as equivalent to species, or to retain varietal names. Still it was difficult to lay down hard and fast rules, applicable to all cases; and he feared that the system of naming varieties was liable to great abuse, especially in entomology, where the number of species is already so great. Thus we have 100,000 species of *Coleoptera* on our lists; and one of the most variable families is that of the *Coccinellidæ*, in which some entomologists have lately begun to name mere colour varieties of single species by twenty and thirty at a time. Mr. Kirby thought, too, that, whenever a named form previously regarded as a variety was held by a later author to be worthy of specific rank, the varietal name should, wherever practicable, always be retained for the species, instead of a new one being imposed. He knew that this was not always adhered to, but in his own work he made it an invariable rule.

Lord Walsingham said that, as Dr. Coues suggested that the trinomial system should be used only in distinguishing gradations, he would instance two species very common in England, small species of the genus *Teras* (*Teras hastiana* and *Teras cristana*). These exhibited a very extensive series of individual variations, but some varieties, although perhaps reared from the same brood of larvæ, showed marked differences not distinctly connected by intermediate gradations with other forms of colouring. He asked how the method was to be applied to these if indeed it was intended to be applied at all to such cases. He himself knew several cases in North America in which variation, according to latitude, is very marked. You get a form in Vancouver Island gradually merging into the form in California, and in Mexico something apparently distinct if taken by itself, and probably only an extreme variety in colour and markings, but you have no form for the South of California. Would it be proposed to treat this Mexican form as a proper subject for the trinomial system or to give it only two names as at present? The principle appears to be right provided it facilitates the recognition of the forms we are naming. He hoped there was no danger of drifting into the inconvenient multiplication of names too commonly known in the catalogues of professional horticulturists.

Dr. Sharp said that whatever names we gave to morphological forms of less than specific value, whether we called them varieties, or sub-species, or morphological forms, we could not define or limit them; and if we attempted to name them, as no line could be drawn, we must go on till we gave a separate name to every individual that had passed through the hands of zoologists. He considered Dr. Coues' system of a third name unnecessary, because all the purposes it sought to attain could be accomplished without it by the old-fashioned system of "var. *a*, var. *b*," and so on. The adoption of a system of names for forms lower than species he thought would lead to complete chaos.

Dr. Woodward, F.R.S., said he might mention two cases which occurred to him in which perhaps the system would be convenient. It was considered desirable by many palæontologists that the group of Ammonites should be broken up into a number of genera, and he thought the present plan of erecting specific names into generic ones was inconvenient. The student was already hampered with too many names, and we ought to remember that students were harder worked now than they were twenty-five years ago. The system of cramming he considered deteriorating to the stamina of the future naturalist. Every time a group was broken up into genera, sub-genera, species, and sub-species, the labour of the student was increased. Therefore it appeared to him that the use of a third term following the generic and specific one, as proposed, was very convenient if not insisted on as a matter of instruction.

Mr. H. T. Wharton would prefer not to see other names troduced unless they were absolutely necessary. But when ell-marked intermediate forms had to be dealt with he admitted the value of the trinomial system, but of course Dr. Coues knew that the method advocated by him was not new to naturalists, for trinomial names were to be found in botanical catalogues. He should be glad to know how it was proposed to deal with such a form as *Corvus cornix*, for example, which in the new edition of Yarrell's "British Birds" had been united with *Corvus corone*.

Mr. H. Saunders said he would like to direct attention to a practical point of the question. Most of those present were aware that there was an unpretending annual called the *Zoological Record*, which consisted now of about 800 pages, and that if trinomialism were adopted, it would make the volume of too great a size. He would also remind those present that Mr. Sharpe was the recorder of Aves, and he did not know how that gentleman would relish the additional labour which would be thrown upon him if this system were generally adopted.

Dr. Traquair said:—I think I quite understand the scope and limits of the system so ably advocated by Dr. Coues, but I feel convinced that were any such system to receive the authoritative sanction of naturalists, these limits would not be observed by the ordinary crowd of name manufacturers. My own studies in recent zoology have been more especially of an anatomical and morphological character, but in the subject of fossil ichthyology I have been brought face to face with the question of the definition and naming of species. Here I conceive that the "species" must include all those forms which can be indubitably shown to graduate into each other. For such species, the only idea of a species which seems to me practicable, one generic and one specific name are quite enough, and I would leave each author to deal with "sub-species" and varieties as he pleased, but without permitting him to apply any *authoritative* name to such. So great, in many cases, is the amount of variation observed in fossil fishes and fish remains, and so difficult is it also to arrive at safe conclusions as to specific identity or distinction with the material before us, that, were the proposed system of trinomial nomenclature to receive the authoritative sanction of naturalists, I am convinced that in this department the flood-gates would simply be opened for a deluge of new names, from people whose sole function in life seems to be to invent such on the most trifling pretext. If the binomial system is at present often abused by such people for the creation of "species" which have no existence, save in their own imaginations, what might we not expect them to do if the adoption of a trinomial system afforded them further scope for their faculties!

Mr. J. E. Harting said if he could be satisfied that the introduction of a system of trinomial nomenclature, as proposed, would be of any real benefit to science, he should have no hesitation in adopting it. But, so far from any advantage resulting from it, he feared that a positive disadvantage would accrue from its adoption in a way which had not been sufficiently considered. The tendency to describe as new species mere individual variations had already (with certain specialists at least) become very p evalent, and had led to an expression of regret and dissatisfaction amongst those who were content to take a broader view of things, and who regarded such a process of refining as tending to perplex, while in no way advancing science. All workers in zoology found themselves sooner or later in one of two classes, which had been named, expressively, if not elegantly, "lumpers" and "splitters." Now, if the proposed system of trinomial nomenclature were to be adopted, the former class would have either to surrender at discretion to the latter, or a wider gap than ever would be created between them, a result which would surely lead to great inconvenience; while the latter, who had already gone to great lengths in what he had termed the process of refining, would receive fresh encouragement to go to still greater lengths in that direction, to the disadvantage, as he conceived, of those who were to come after them. We had been told by the advocates of the trinomial system that it was impossible not to recognise climatic variations in any given species when they were found to be constant and well marked. In this he agreed: he only dissented from them in regard to the mode by which such recognition was to be effected. To say that the only mode of recognising such variations was to add a third name to the generic and specific names was begging the question. If any such variation as that alluded to was sufficiently well marked to distinguish it at once from the species of which it was said to be a variety, he would prefer to regard it as an allied species, and bestow on it a specific name, retaining a binomial nomenclature. The binomial system had been found to work well enough in practice, from its simplicity; and it was

surely simpler to write *Turdus propinquus* than *Turdus migratorius propinquus*. After all, nomenclature was not science, and even if we had the most perfect system of nomenclature which could be devised, he did not see how science would be thereby advanced. It is true we could not get on without nomenclature, but the simpler it was the better; aud the less time we spent in discussing it the more we should have to devote to real study.

Dr Coues, replying to previous speakers, said that the system of trinomial nomenclature had nothing whatever to do with individual variations of specimens from one locality. It was not a question of naming varieties or hybrids, but there was a definite principle to proceed upon, namely, that of geographical and climatal variation. He was well aware that the use of three names to designate objects in zoology was no new thing; but he believed that the restricted application of trinomialism to the particular class of cases he had discussed was virtually novel, and that his system would prove to be one of great practical utility. He thought that the application of the principle was a question which, after this discussion, and after further private discussions, might well be left to the discretion of authors.

The Chairman concluded the meeting by saying:—I hope that Dr. Elliott Coues is satisfied with the manner with which his views have been received. Although there are some uncompromising binomialists present, many have pronounced themselves as what may be termed limited trinomialists, and some appear to go as far as Dr. Coues himself. Distinctly defined species undoubtedly exist in great numbers, owing to extinction of intermediate forms; for these the binomial system offers all that is needed in defining them. But on the other hand there are numbers of cases in the actual state of the earth, and far more are being constantly revealed by the discoveries of palæontology, and nowhere so rapidly as in Dr. Coues' own country, where the infinite gradations defy the discrimination either of a binomial or a trinomial system. Zoologists engaged in the question of nomenclature are being gradually brought face to face with an enormous difficulty in consequence of the discovery of these intermediate forms, and some far more radical change than that now proposed will have to be considered. In conclusion I must express the thanks of the meeting to Dr. Coues for having brought his views and those of his countrymen, of whom he is such a worthy representative, before us, and also to Mr. Bowdler Sharpe, to whose zeal and energy the organisation of the meeting is entirely due.

A unanimous vote of thanks was given to Prof. Flower for presiding.

KRAKATOA

AT the meeting of the Meteorological Society of Mauritius on May 22 some interesting communications were made relating to the Krakatoa eruption. Among others was a letter from M. Lecomte regarding detonations heard at Diego Garcia on August 27. In his letter, which was written at Diego Garcia on April 24, M. Lecomte says:—"Le lundi 27 août entre 10 et 11 heures du matin, pendant le déjeûner, nous avons entendu des détonations sourdes mais violentes. Nous avons cru tellement à l'appel d'un navire en détresse que nous avons couru et que j'ai envoyé plusieurs hommes vers le rivage extérieur de l'île sur plusieurs points différents, en observation. Le Capitaine Florentin de l'*Eva Joshua* et son second, M. Daniel Sauvage, venaient de quitter Pointe de l'Est pour aller mouiller à Pointe Marianne, lorsqu'ils ont entendu les mêmes détonations. Ils ont aussitôt envoyé des hommes en observation à l'extrémité des mâts. Mais comme les miens ils n'ont rien vu.

"Ce jour là et les jours suivants le soleil était comme obscurci, probablement par la formidable quantité de vapeurs et de cendres qui ont du s'élever dans l'atmosphère."

The information obligingly furnished by M. Lecomte was valuable, inasmuch as, take n in conjunction with the reports which had been received from Rodrigues, it confirmed verbal information which had been previously obtained. There could now be no doubt that the explosions which took place at Krakatoa were distinctly heard both at Diego Garcia and Rodrigues, and there was probably no other recorded instance of sound having travelled over so great a distance. The fact, also, that at Diego Garcia the sun was partially obscured on August 27 and on several subsequent days, as well as at the Seychelles and Rodrigues, was an additional proof of the great quantity of matter which must have been ejected from Krakatoa, and of the rapidity with which it was conveyed from its source. There could be no reasonable doubt that the presence of that matter in the atmosphere was the cause of at least the lurid sunsets and sunrises which were observed over the Indian Ocean on the last days of August and in the first week of September.

The Secretary, Dr. Meldrum, stated that the Royal Society of London had appointed a Committee to collect information regarding the phenomena which had been observed during and after the volcanic eruptions that took place at Krakatoa in August, and requests had been received from that and other quarters for information from Mauritius. To these requests the Secretary had replied that he was preparing for his Excellency the Governor a detailed account of what had been observed at Mauritius and several of its dependencies, but that owing to the almost daily reception of additional details his report was not yet ready. All he did, therefore, was to give the general results as far as they had been determined.

Several remarkable phenomena had to be described. In the first place, there were disturbances of the sea water, or, as they had been called by some, tidal disturbances, and these had been observed all over the Indian Ocean.

There were also barometric disturbances, to which attention had first of all been called in Mauritius early in September, and which at the time were ascribed to the explosions at Krakatoa. Some time afterwards it was ascertained in England that these disturbances had extended over the whole globe and that they were recorded by all self-registering barometers in both hemispheres. At Mauritius there were at least seven well-marked disturbances of which the epochs of *maximum intensity* were as follows:—

			h. m.		
(1)	August	27,	0.6	p.m.	local time.
(2)	,,	28,	2.20	p.m.	,,
(3)	,,	28,	10.40	p.m.	,,
(4)	,,	30,	1.35	a.m.	,,
(5)	,,	30,	9.17	a.m.	,,
(6)	,,	31,	1.48	p.m.	,,
(7)	,,	31,	8.00	p.m.	,,

At first these disturbances were supposed in Mauritius to have been due to successive eruptions, but General Strachey, who examined a number of barographs received from different parts of the world, had recently adduced evidence to show that they were produced by an air-wave proceeding outwards from Krakatoa in all directions round the earth, expanding till it was half round, then contracting till it reached the antipodes of its origin, and afterwards returning, the wave thus travelling round the globe two or three times. Assuming that view, the first disturbance at Mauritius (which was at its maximum at oh. 6m. p.m. on the 27th) would be caused by the passage over the Observatory of the wave travelling from east to west; and the third, fifth, and seventh disturbances would be returns of the wave to Mauritius after having gone round the earth. Similarly the second disturbance would be the first passage of the wave travelling from Krakatoa eastward, and the fourth and sixth would be its returns to Mauritius. Now, the mean interval in time between the returns of the wave to Mauritius, in its passage from east to west, was 24h. 38m., and in its passage from west to east 35h. 44m. It would thus appear that the rate of progression had been greater from east to west than from west to east, which may have been partly or wholly due to the great circle passing through Krakatoa and Mauritius being within the tropics, where the prevailing wind was from the eastward. The rate of progression from east to west was very nearly 709 miles an hour, and from west to east 697 miles. By taking as nearly as possible the times half way between the commencements and endings of the disturbances similar results were obtained. There was also an *eighth* (but small) disturbance between 7 and 9 a.m. on September 2, which may have been the fourth return of the wave from east to west, the interval in time between that disturbance and the seventh having been nearly thirty-six hours. The sixth disturbance was the last indication of the wave in its passage from west to east.

Another effect of the Krakatoa eruptions was the spread of ashes and pumice over considerable portions of the Indian Ocean, and a good deal of information on that point also had been collected in Mauritius. The first intimation of the probability of volcanic action in the direction of the Straits of Sunda was contained in a letter published by Capt. Walker, of the *Actæa* in the *Mercantile Record* of June 16, 1883. At noon on

May 20 the *Actæa* was in 6° 50′ S. and 104° 2′ E., and on the morning of that day a "peculiar light green colour" was observed in the sky to the east-south-east, while "from east to east-north-east there was a dark blue cloud, which reached from the horizon to the zenith." "About 2 p.m. it was quite dark. What appeared to be a rain squall rose up from the east, but, instead of rain, a kind of very fine dust commenced to fall, and very soon everything was covered; ships, sails, rigging and men were all dust colour; nothing could be seen 100 yards off. The fall continued steadily all night, and stopped about 9 a.m. on Monday the 21st. When we saw the sun it looked like dull silver. At noon we were in lat. 8° 15′ S. and long. 102° 28′ E., distant from Java Heads about 170 miles. The sky all round remained a dusty hue, and small quantities of dust again fell during the night. The sky did not assume a natural appearance till the 23rd." At a meeting of this Society held on July 12, the Secretary called attention to Capt. Walker's letter, and said there was little doubt that the dust in question had come from Krakatoa, as, according to a note in NATURE of June 7, a volcano in that island was in full eruption. From that time accounts of pumice and ashes observed in the Indian Ocean had been extracted from log-books, and they showed that on several occasions vessels had passed through fields of pumice long before the great eruptions of August 26 and 27. After that month the reports became more frequent, and they still continued, the latest being from the vicinity and shores of Mauritius, where, since the middle of February, large quantities of pumice had been seen. It would appear, however, that fields of pumice had passed Mauritius long before February, for "a large quantity of pumice-stone and lava was washed up on the beach at Durban (Natal) on October 23." According to the reports received, fields or lanes of pumice had been observed in different parts of the Ocean from 105° to 48° E. and 6° to 12° S. Farther south the extent in longitude had been apparently less.

That the remarkable sunrises and sunsets which had been observed over a great part of the world after August 27 were due to matter ejected from Krakatoa seemed to be generally admitted. The few who objected to the volcanic dust theory had not proposed any other theory that so completely accounted for the facts. The presence of vapours and finely-divided dust at certain elevations would, as a consequence of known physical laws, produce all the chromatic effects that had been seen and described, and it was known that immense quantities of matter had been shot up from Krakatoa. Similar phenomena had been witnessed by observers between whom and the sun volcanic dust passed, as on the occasion of an eruption of Cotopaxi a few years ago. But it was not necessary to go so far back. From May 20 to 22 last, after an eruption of Krakatoa, Captain Walker, as already stated, observed that to the east-south-east the sky was of a light green colour, that on the 21st the sun looked like dull silver, that the sky all round was of a dusty hue, and that it did not assume its natural appearance till the 23rd. That was perhaps the earliest instance of the chromatic effects of the Krakatoa dust and vapours. Immediately after the eruptions of August 27 they were more intense and on a greater scale. At the Seychelles on the 27th the sky, according to Mr. Estridge, was hazy all day. The sunset on that day was gorgeous; the sky was lurid all over, and beams of red light stretched from over St. Anne's to nearly the horizon. At sunset on the 28th the sun looked as it did through a fog on a frosty day in England. On the morning of the 29th the sun at 7 a.m. was more like a full moon than anything else. According to other letters from the Seychelles the sun for a whole week appeared dim. At Rodrigues, according to Mr. Wallis, whose report was written on August 31, the sky at north-west on every evening since the 27th had a very threatening and strange appearance of a deep purplish red colour, which lasted till 7.15 p.m., and which, with the disturbances of the sea water, caused much fear and excitement. Similar phenomena were observed on the same evenings at Diego Garcia and St. Brandon, and for several days the sun looked as if partially obscured. At Mauritius the sky was overcast throughout the whole of the 27th, and it was observed and noted at the time that there was an unusual dimness. On the evening of the 28th there was a gorgeous sunset, the first of a long series of remarkable colorations and glows, which had already been described. Observations of these optical phenomena had been taken daily during nearly the last nine months whenever the weather permitted. Knowing what had been observed on board of the *Actæa*, and that Krakatoa had been in eruption, these extraordinary sunsets and sunrises were attributed to the presence in the upper strata of the air of finely-divided matter, and probably gases and vapours, from Krakatoa, and subsequent events confirmed that opinion. It was difficult to explain phenomena which had been identical under all conditions of weather, and in many distant places, by any purely meteorological causes. To the meteoric dust theory it might be objected that it was purely an hypothesis almost, if not wholly, unsupported by facts. No unusual number of meteors had been seen. No extraordinary glows had been observed at or near the times of the great meteoric showers of November 1866, and November 1872. Moreover one would suppose that if the earth had for months been passing through volumes of meteoric dust the chromatic effects would have appeared simultaneously wherever the sun rose and set. But such had not been the case. Upon the whole there seemed to be a preponderance of evidence in favour of the volcanic dust theory. The objection that the quantity of matter was insufficient was not a formidable one, for the effects did not depend merely upon the quantity of matter that had reached the higher regions, but also upon its form and degree of tenuity. A few pounds of matter might be spread over thousands of square miles. As to the objection that it was difficult to conceive how even finely-divided matter could remain so long in suspension, it might be remarked that, independently of the possibility of the particles being electrified, the lower strata of the atmosphere might be denser than the foreign matter in the upper strata. The extraordinary sunsets and sunrises which were observed in 1783-84, and which Arago and others ascribed to volcanic dust, were said to have lasted eleven months. Those of 1883-84 would probably last fully as long. Within the last few weeks there had been at Mauritius a considerable increase in the intensity and duration of the glows.

EVIDENCES OF THE EXISTENCE OF LIGHT AT GREAT DEPTHS IN THE SEA[1]

THE evidences of the presence of light and its quality and source at great depths are of much interest. At present very little experimental knowledge in regard to these questions is available. That light of some kind, and in considerable amount, actually exists at depths below 2000 fathoms, may be regarded as certain. This is shown by the presence of well-developed eyes in most of the fishes, all of the cephalopods, most of the decapod Crustacea, and in some species of other groups. In many of these animals, living in 2000 to 3000 fathoms, and even deeper than that, the eyes are relatively larger than in the allied shallow-water species; in others the eyes differ little, if any, in size and appearance, from the eyes of corresponding shallow-water forms; in certain other cases, especially among the lower tribes, the eyes are either rudimentary or wanting in groups of which the shallow-water representatives have eyes of some sort. This last condition is notable among the deep-water gastropods, which are mostly blind; but many of these are probably burrowing species; and it may be that the prevalent extreme softness of the ooze of the bottom, and the general burrowing habits, are connected directly with the habits or rudimentary condition of the eyes in many species belonging to different classes, including Crustacea and fishes. Such blind species usually have highly developed tactile organs to compensate for lack of vision.

Other important facts bearing directly, not only on the *existence*, but on the *quality*, of the light, are those connected with the coloration of the deep-sea species. In general, it may be said that a large proportion of the deep-sea animals are highly *coloured*, and that their colours are certainly *protective*. Certain species, belonging to different groups, have pale colours, or are translucent, while many agree in colour with the mud and ooze of the bottom; but some, especially among the fishes, are very dark, or even almost black; most of these are probably instances of adaptations for protection from enemies, or concealment from prey. But more striking instances are to be found among the numerous brightly-coloured species belonging to the echinoderms, decapod Crustacea, cephalopods, annelids, and Anthozoa. In all these groups, species occur which are as highly coloured as their shallow-water allies, or even more so. But it is remarkable that in the deep-sea animals the bright colours are almost always shades of orange and orange-red, occasionally brownish red,

[1] From a paper in *Science*, July 4, on "Results of Dredgings in the Gulf Stream Region by the U. S. Fish Commission."

purple, and purplish red. Clear yellow, and all shades of green and blue colours, are rarely, if ever, met with. These facts indicate that the deep sea is illuminated only by the sea-green sunlight that has passed through a vast stratum of water, and therefore lost all the red and orange rays by absorption. The transmitted rays of light could not be reflected by the animals referred to, and therefore they would be rendered invisible. Their bright colours can only become visible when they are brought up into the white sunlight. These bright colours are therefore just as much protective as the dull and black colours of other species.

The deep-sea star-fishes are nearly all orange, orange-red, or scarlet, even down to three thousand fathoms. The larger ophiurans are generally orange, orange-yellow, or yellowish white, the burrowing forms being usually whitish or mud-coloured, while the numerous species that live clinging to the branches of gorgonians and to the stems of Pennatulacea are generally orange, scarlet, or red, like the corals to which they cling. Among such species are *Astrochele lymani*, abundant on the bushy orange gorgonian coral, *Acanella normani*, often in company with several other orange ophiurans belonging to Ophiacantha, &c. *Astronyx loveni* and other species are common on Pennatulacea, and agree very perfectly in colour with them. These, and numerous others that might be named, are instances of the special adaptations of colours and habits of commensals for the benefit of one or both. Many of the large and very abundant Actiniæ, or sea-anemones, are bright orange, red, scarlet, or rosy in their colours, and are often elegantly varied and striped, quite as brilliantly as the shallow-water forms; and the same is true of the large and elegant cup-corals, *Flabellum goodei*, *F. angulare*, and *Caryophyllia communis*,—all of which are strictly deep-sea species, and have bright orange and red animals when living. The gorgonian corals of many species, and the numerous sea-pens and sea-feathers (Pennatulacea), which are large and abundant in the deep sea, are nearly all bright coloured when living, and either orange or red. All these Anthozoa are furnished with powerful stinging organs for offence and defence; so that their colours cannot well be for mere protection against enemies, for even the most ravenous fishes seldom disturb them. It is probable, therefore, that their invisible colours may be of use by concealing them from their prey, which must actually come in contact with these nearly stationary animals in order to be caught. But there is a large species of scale-covered annelid (*Polynoë aurantiaca*, Verr.) which lives habitually as a commensal on *Bolocera tuediæ*, a very large orange or red actinian, with unusually powerful stinging organs. Doubtless the worm finds, on this account, perfect protection against fishes and other enemies. This annelid is of the same intense orange colour as its actinian host. Such a colour is very unusual among annelids of this group, and in this case we must regard it as evidently protective and adaptive in a very complex manner.

It has been urged by several writers, that the light in the deep sea is derived from the phosphorescence of the animals themselves. It is true that many of the deep-sea Anthozoa, hydroids, ophiurans, and fishes are phosphorescent; and very likely this property is possessed by members of other groups in which it has not been observed. But, so far as known, phosphorescence is chiefly developed in consequence of nervous excitement or irritation, and is evidently chiefly of use as a means of defence against enemies. It is possessed by so many Anthozoa and acalephs which have, at the same time, stinging organs, that it would seem as if fishes had learned to instinctively avoid all phosphorescent animals. Consequently it has become possible for animals otherwise defenceless to obtain protection by acquiring this property. It is well known to fishermen that fishes avoid nets, and cannot be caught in them, if phosphorescent jelly-fishes become entangled in the meshes; therefore it can hardly be possible that there can be an amount of phosphorescent light, regularly and constantly evolved by the few deep-sea animals having this power, sufficient to cause any general illumination, or powerful enough to have influenced, over the whole ocean, the evolution of complex eyes, brilliant and complex protective colours, and complex commensal adaptations.

It seems to me probable that more or less sunlight does actually penetrate to the greatest depths of the ocean in the form of a soft sea-green light, perhaps at two thousand to three thousand fathoms equal in intensity to our partially moonlight nights, and possibly at the greatest depths equal only to starlight. It must be remembered that in the deep sea, far from land, the water is far more transparent than near the coast. A. E. VERRILL

ARTIFICIAL LIGHTING[1]

In early times but a small fraction of our forefathers' lives was spent under artificial light. They rose with the sun and lay down to rest shortly after sunset. During the long winter evenings they sat round the fire telling stories and singing songs of love and war; the fire-light was sufficient for them, except occasionally during grand feasts and carousals, when their halls were lighted by pine-wood torches or blazing cressets. But, as a rule, after sunset they lived in semi-darkness.

From that early period, as man has advanced in civilisation, in the thirst for knowledge derived from books, and in following the gentler pursuits which demand an indoor life, there has been a steady increase in that fraction of our lives which is spent under light other than that of the sun. But the improvement in the quality of the artificial light has been very slow. The ruddy lights and picturesque shadows so faithfully handed on to us by Rembrandt's pictures show us very graphically what our poets have called "the dim glimmer of the taper" of those days. A few years before the introduction of gas, Argand, by his improvements in the burners of oil lamps, enabled our fathers to see for the first time a comparatively white light, but as far as the matter we to-day propose to discuss is concerned, viz. the effect of artificial lighting, and more particularly electric lighting, on our health, we need only consider the reign of artificial light as it commenced with the general use of gas and petroleum, for then and only then could it be said to affect our health.

Prior to the introduction of the electric light we have been accustomed to consider every hour spent under artificial light as an hour during which all conditions are less favourable to perfect health than they would be during daylight. Can we now hope to ameliorate this condition of things through the agency of electricity? Before we can discuss this question I must point out to you the chief differences which exist between hours of work or recreation spent in daylight and under artificial light. In the former case we live in abundance of light. The sunlight itself exercises a subtle influence on our bodies; that mixture of heating and chemical rays which when analysed form the solar spectrum, and combined form the pure white light of daylight, is needed to enable all animal and vegetable organisms to flourish in the fullest conditions of healthful life.

In nearly all cases when the sun is up, the functions of life are in the state of fullest activity, and when it sets they sink into comparative repose. In daylight life wakes, in darkness life sleeps. In addition to the abundance of pure white light, the heat attending is only that necessary for health. The air remains unvitiated, except by our own breathing. On the other hand, when working under artificial light, we have these conditions all altered in degree:

1. We have an insufficient light; a scale of lighting by gas or by electricity which would be pronounced excessive at night-time is still far inferior to average daylight.

2. All artificial lights, whether produced by combustion, as in the case of candles, oil, gas, and petroleum, or by the incandescence of a conductor by the means of electricity, produce heat; this heat, in proportion with the light afforded, is enormously in excess of the heat given by sunlight. Electricity, as you will see hereafter, is far the best in this respect, but even it is inferior to sunlight.

3. All these same illuminants, excepting electricity, contaminate the air and load it with carbonic acid, sulphur, and other compounds—all injurious to the health and to the general comfort of the body. It will be convenient to consider the effects —first, on our health generally; second, on our eyesight in particular. I have already called your attention to the fact that that proportion of coloured rays which, when combined, form white sunlight, is that best suited to healthy life. It is necessary too to that sufficient and proper stimulus to the organic changes which go on in our bodies, and which we call a state of good health. The various artificial lights differ very widely from sunlight in this respect, that they are all more or less deficient in the rays at the violet end of the spectrum, commonly called the actinic rays, and which most probably exercise a very powerful effect on the system. It is the want of a due portion of these violet rays which makes all artificial light so yellow. Even the light of the electric arc, which is richer in these rays than any other, is still on the yellow side of sunlight. The incandescent electric light is next best in this respect; next in order come gas, petroleum, and the various oil lamps. No doubt some of you will

[1] Lecture delivered at the Health Exhibition by Mr. R. E. B. Crompton

challenge my statement that the electric arc is yellow. It has always been called a cold blue light. It is not so; it is only by comparison with the yellower light of gas or with the incandescent lamps that it appears blue; when compared with the sunlight reflected from a white cloud it will be seen to be distinctly yellow in tinge; but still both classes of electric light are far superior to all others in nearest approaching the white light of daylight, and thus satisfying the actinic action which our bodies demand.

Turning now to the comparative heating and air-vitiating properties of artificial lights which we shall find it convenient to take together, I have here a table (Table A) prepared by Dr.

TABLE A.—*Showing the Oxygen consumed, the Carbonic Acid produced, and the Air vitiated, by the Combustion of certain Bodies burnt so as to give the Light of 12 Standard Sperm Candles, each Candle burning at the rate of 120 grains per hour*

Burnt to give light of 12 candles, equal to 120 grains per hour	Cubic feet of oxygen consumed	Cubic feet of air consumed	Cubic feet of carbonic acid produced	Cubic feet of air	Heat produced in lbs. of water raised 10° F.

Electric Light.			none	none	13·8

Meymott Tidy, which shows the oxygen consumed, the carbonic acid produced, the air vitiated, and the heat produced by the combustion of certain bodies burned so as to give the light of twelve standard candles, to which Mr. R. Hammond has added the heat produced by a 12-candle incandescent electric lamp. From these figures you will see that the air of a room lighted by gas is heated twenty times as much as if it were lighted to an equal extent by incandescent electric lamps. When arc lamps are used, the comparison is still more in favour of electricity. You will be surprised to see from the table that our old friend the tallow candle, and even the wax candle, is far worse than gas in the proportion of air vitiated and heat produced, and you will be disposed to disbelieve it; but the fact is, that so long as candles were used light was so expensive that we were obliged to be content with little of it; in fact we lived in a state of semi-darkness, and in this way we evaded the trouble. It is only since the general introduction of gas and petroleum that we have found what an evil it is.

It is not unusual, in fact it is almost invariable, for us to find the upper stratum of air of the rooms in which we live heated to 120° after the gas has been lighted for a few hours. We have grown accustomed to this state of things, and are not surprised that when we take the library ladder to get a book from the upper shelf we find our head and shoulders plunged into a temperature like that of a furnace, producing giddiness and general malaise. If you look again at the table you will see that each gas burner that we use consumes more oxygen and gives off more carbonic acid, and otherwise unfits more air for breathing, than one human being, and it is this excessive heating and air vitiation combined which are the main causes of the injury to the health from working long hours in artificial light. I could go on for a long time giving instances of the fearful state of the atmosphere of our large public buildings as well as of our private homes after the gas has been lighted for a few hours, but this paper is not intended as an onslaught on gas; moreover these ills are so well known to nearly all of you that I need not bring them more prominently before you. I will only take one instance, viz. that of the Birmingham Town Hall, which has been lighted alternately by gas and electricity.

During the grand Birmingham Musical Festival, which was held in that hall two years ago, some careful experiments were made to show how the orchestra and audience in the hall were affected by the two kinds of lighting. The gas lighting was in the form of several huge pendants suspended down the centre of the hall. The electric lighting was in the form of clusters of lights placed on large brackets projecting from the side walls with two central pendants placed between the gas pendants. The candle-power given by the electric light was about 50 per cent. in excess of that given by the gas light; the degree of illumination by electricity was consequently very brilliant.

It was found that when the gas was used the temperature near the ceiling rose from 60° to 100° after three hours' lighting. The heating effect of the gas was, therefore, the same as if 4230 persons had been added to the full audience and orchestra of 3100. Similarly the vitiation of the air by carbonic acid was equal to that given off by the breathing of 3600 additional persons added to the above audience of 3100. But on evenings when the electric light was used the temperature only rose 1½° during a seven hours' trial, and the air, of course, was only vitiated by the breathing of the audience. The further experiment was tried of giving to every member composing the large orchestra a printed paper of questions asking how the new mode of lighting affected him or her personally, and I have here 265 replies to those questions. They are very interesting. I will read a very few of them out to you. From this you will learn that without exception the comfort and general well-being of this large orchestra was increased enormously by the use of the new illuminant, yet it is reasonable to suppose that the comfort of the audience was increased in an equal degree. Now we all of us know that the times when we suffer most from the effect of artificial light is in crowded places of public amusement, which are at the same time brilliantly lighted. Many of us are unable to go to the theatre or to attend evening performances of any kind, as the intense headache which invariably attends through staying a single hour in such places entirely prevents them. This headache we commonly say is inseparable from the heat and glare of the gas. Now this phrase is not strictly correct. It is no doubt due to the heat of the gas and its air-vitiating properties, but when we use the word glare I believe we refer to the effect the gaslight has upon our heads, and which effect is not due to excess of light. On the contrary, I believe if a far greater amount of light be given by the electric light without the heating and air vitiation being present such headache is never produced, although some of the more tender-headed amongst us will at first complain of the glare because they are habituated to associate plenty of light with great heat, great air vitiation, and other evils.

Indeed, so long have we been accustomed to closely associate brilliant artificial light with headache and glare, that we who are introducing electric light are most cautious not to give the full quantity of light which we could afford to give, and which would afford the greatest rest to the eye and greatest bodily comfort. I now come to the effect that light has upon the temperament. If we try the experiment in an assemblage of people of gently decreasing the lighting of the room, it will be found that the spirits of every one will be depressed just as the light is depressed, and, *vice versâ*, their spirits will be raised just as the light is raised. I have many times, when conducting experiments of electric lighting on a large scale, noticed this fact, and I have been led to the conclusion *that during hours of waking every person is benefited by increase of light up to the extent of full sunlight*, providing that this high degree of lighting is not attended by heat and by air vitiation; and I must add that the source of light must not be from one or two brilliant points only, but it must be well regulated and not such as to cause dark, deep shadows.

This leads me on to the subject of the effects on the eyesight of the electric light as compared with other lights. *Healthy eyesight demands a plentiful supply of light. It is the greatest mistake to suppose that a state of semi-darkness is good* for our eyes, unless they are defective, or recovering from the effects of past injury or disease. Whoever saw a painter, engraver, printer, watchmaker, or indeed any one the quality of whose work depends on the excellence of his eyesight, who did not desire a flood of pure white light thrown on to his work. I think I have the authority of oculists when I say that 19-20ths of the diseases of the eyes arise from working the eyesight long hours with insufficient light. Again, another great cause of injury to eyesight is the unsteadiness of most artificial lights. Much improvement has been made in the light of gas during the

last few years by the introduction of argand burners, and globes for the flat gas burners having much larger lower openings, so that the dancing and flickering batswing burner of five years ago is not so common in a good house. Even the steadiest of the modern gas burners is extremely unsteady as compared with the light of the incandescent electric lamp. Those of you who have been to the Savoy Theatre will have noticed the effects of the lights behind the scenes on the scenery itself. The light is so absolutely steady that it is comparable to sunlight. Hitherto I have said nothing as to the comparative excellence of the two forms of electric light, viz. the electric arc and the incandescent lamp. Both have *their* proper places. The arc light, which is the whitest in colour and most economical to produce, is not so steady as the incandescent lamp. It is therefore unsuitable for indoor use or for reading by, or for such occupations as require the maximum of steadiness. But it is well suited for the lighting of large buildings and public places. I am unaware if any experiments have been made as to the effects of brilliant arc lighting on the eyesight of men who have to work night shifts, as although the opinion of the workmen who have to work under it is unanimous in its favour, yet that opinion is more based on their personal comfort, due to their being able to carry on their work with facility almost equal to that given by daylight. The large sorting rooms at the General Post Office at Glasgow have been for a long time lighted by the arc light, and with a most beneficial result to the health and eyesight of the letter-sorters and telegraph clerks. The former occupation is one which tries the eyesight very severely. The public generally does not know how the habit of writing the addresses on envelopes with pale ink and blotting it off rapidly before it has time to darken tries the eyesight of the Post Office letter-sorters. So long as gas is used, a powerful burner has to be brought very close to the head of the sorter, and under such conditions the eyesight fails at an early age. At Glasgow Post Office I am able to boast that by the introduction of the electric light I enabled many of the more aged sorters who were commencing to use spectacles to do without them—and even I put back the clock of time in enabling several who had used them for some years to disclaim them. I am aware that it has been alleged by the opponents of the electric light, whether interested or otherwise, that in many cases the intensity of the light has injured eyesight. I do not think any such cases can be substantiated. Many of us who are in the habit of experimenting with powerful arc lamps have had our eyelids temporarily affected by incautious exposure at too short a distance. Again, over and over I meet with the complaint that if I stare at an arc lamp for a long time it will make my eyes ache; the obvious retort being, Why should you stare at the light? If you do the same with the sun, you will be equally inconvenienced. Before such an audience as this, which is of course familiar with the beautiful electric lighting in the Health Exhibition itself, it is useless for me to enlarge on the many conditions of the electric light as it indirectly affects health. I may only name the many additional pleasures of the eye we get from its use. Our flowers in our rooms do not fade away, and are seen in their true colours. Our pictures or all coloured objects are seen to better advantage. I may mention one thing which would not generally occur to you, that in London certainly an electric-lighted house can be cleaned properly in winter. You may smile at this, but I assure you that the advantage of being able to turn a flood of light into your drawing-rooms and dining-rooms at six o'clock on a winter's morning, so that the whole of the cleaning can be finished as thoroughly as if done by daylight, before the family comes down to breakfast, is one that must be experienced before it can be thoroughly appreciated. Again, the advantage to the health of our children is simply inestimable. No night-lights, matches left about, or gas turned down low are required. A child six years old can be trusted to press a button and so turn the light off or on; the lamps being high and out of reach are not easily broken or over-turned, and the air of the children's nursery, even if the light be kept burning the night through, remains pure throughout. Another indirect advantage due to the absence of heat is that it is comparatively easy to thoroughly ventilate and cool during the hot weather a room lighted by the electric light. The heat of gas placed high in the room causes such intense draughts when the windows are open that the discomforts and dangers of the draughts are almost worse than the discomfiture from the heat and vitiated air, whereas in an electric-lighted room there is no difficulty in opening wide all the windows, the draughts produced being so gentle as to be hardly felt.

SOCIETIES AND ACADEMIES

London

Physical Society, June 28.—Prof. Guthrie, President, in the chair.—New Member, Mr. W. H. Hensley.—Lord Rayleigh made a communication on the practical use of the silver voltameter for the measurement of an electric current. On a former meeting of the Society the method was explained by the author, but on the present occasion the apparatus was exhibited. The author considers this the best method of determining the strength of current in absolute measure. One ampere deposits 4 grammes of silver in an hour; therefore a quarter to half an hour is sufficient to give 1 or 2 grammes, quantities which can be measured with accuracy. Any current from 1/10 to 4 or 5 amperes can be measured successfully in this way. With very weak currents there is a difficulty in weighing the deposits; with very dense currents the deposit is apt to be irregular. The author deprecates the use of acetate of silver, pure nitrate or pure chlorate of silver giving the best results. The cathode of his apparatus is a platinum bowl, the anode a silver sheet wrapped with clean filter paper sealed over it to keep any loose silver from dropping on the cathode. The anode is immersed in the solution of silver salt; and at the end of several hours (if great accuracy is required) a measurement of the weight of silver deposited is made by weighing the bowl cathode in a chemical balance. Dr. Fleming inquired whether it was not better to weigh the loss of weight suffered by the anode, as is sometimes done. Lord Rayleigh had not found this plan so good, the anode being apt to disintegrate and lose weight, not by true electrolytic action. Prof. Guthrie remarked that with small electrodes peroxide of silver is formed, and that the inferiority of acetate of silver might be due to formation of subacetate.—Lord Rayleigh then made a communication on a colour-mixing apparatus founded on refraction. This apparatus had been described at a former meeting of the British Association, and consists of a double-refracting prism, a lens, dispersing prism, and screen, by which an overlapping of spectra can be obtained, and thus a mixture of colours. In comparing different cyesights with it Lord Rayleigh finds that the majority of persons are more sensitive to red than he himself. In answer to Mr. W. Baily he had not observed any difference between the two eyes of the same person, except what might be due to fatigue and freshness. Dr. Guthrie inquired if the author had discovered any racial characteristics of colour-blindness. Lord Rayleigh had not observed any so far. Dr. Guthrie stated that, though colour-blind to red, he believed he was more than usually sensitive to blue. Dr. Stone and Mr. Stanley referred to known cases of blindness to green, as well as red. Dr. Lodge asked if persons abnormally sensitive to red could see further down the spectrum. Lord Rayleigh believed they could see the spectrum brighter near its limits at all events. Mr. Glazebrook briefly described a modification of Lord Rayleigh's apparatus by which the distance on the spectrum which any one can see could be measured.—Mr. C. V. Boys read a paper on a phenomenon of electro-magnetic induction. Between the poles of an electro-magnet a small disk of copper is hung by a bifilar suspension. If the magnetic field is uniform, and the disk at an angle to the lines of force, then on making the magnet it is jerked parallel with the lines of force. If it is a changing field, and the disk perpendicular to the lines of force, it is repelled on making the magnet and attracted on breaking by the nearest pole. This phenomenon, which was observed by Faraday, was shown by Mr. Boys to be useful for determing the intensity of a magnetic field by measuring the throw of the disk on magnetising and demagnetising. It might also be employed to measure the resistance of bodies in the form of plates, from their diameter, moment of inertia, and observed throw. Any structural difference of resistance in different directions in the body might be determined by its means. Mr. Boys illustrated his remarks with curves of results obtained by experiment. Lord Rayleigh considered that the effect of self-induction on the results was not likely to be serious.—Mr. J. Hopps read a paper on the alteration of electrical resistance in metal wires produced by coiling and uncoiling. His experiments were made with an inclined plane, the angle of which could be varied, and a car, carrying bobbins, which was drawn up or let down the plane by the wires experimented on. It appeared that coiling and uncoiling tends to produce hardness in a wire. Coiling produces an increase of resistance, and uncoiling a decrease in the resistance of a wire.—Mr. R. T. Glazebrook, M.A., F.R.S., read a paper on the determination

in absolute measure of the electrical capacity of a condenser, and on a method of finding by electrical observations the period of a tuning-fork. The paper described experiments conducted according to a method given in "Maxwell," vol. ii. § 776, for measuring the capacity of a condenser. Mr. J. J. Thomson showed (*Philosophical Transactions*, 1883, part iii.) that Maxwell's formula is only approximate, and gave the correct formula, which was used in the author's experiments. In these tuning-forks were used of frequencies approximately 16, 32, 64, and 128 to a second, the frequencies being determined by careful comparison with the clock by Lord Rayleigh's method, and the corresponding values found for the capacity were ·3336 m.f., ·3340 m.f., ·3335 m.f., ·3337 m.f. The mean is ·3337 m.f., and the experiments do not show any variation in the capacity, as the time of changing varies from 1/16 to 1/128 of a second. The condenser was furnished by Messrs. Latimer Clark, Muirhead, and Co. The method also gives a ready and accurate means of determining the pitch of a tuning-fork, for if the capacity of the condenser used is known the frequency (n) can be determined. The author has used the method successfully for this purpose. Lord Rayleigh objected to mercury contacts in such experiments; and Dr. Stone said he had found iron and mercury contacts good.—Prof. Herbert Macleod exhibited a sunshine recorder made by placing a water lens in front of a camera box and lens. Sensitised paper is placed in the bottom of the box so that the focused ray strikes on it, and as the sun moves traces a curved line or band on the paper. Several of these records were shown to the meeting.

Royal Microscopical Society, June 11.—Rev. W. H. Dallinger, F.R.S., President, in the chair.—Prof. Zenger's method of constructing endomersion objectives by using a mixture of ethereal and fatty oils for correcting chromatic aberration was explained and an objective exhibited.—Dr. Wallich exhibited a new condenser which he had devised.—Mr. J. Mayall, jun., exhibited and described his method of applying amplifiers to a microscope, by which a considerable range of magnifying power and working distance was obtained.—Mr. C. Beck exhibited and described a new form of microscope lamp for use in various pathological and physiological investigations.—Notes were read on human spermatozoa with two tails (Mr. Hazlewood), on the potato-blight insect (Mr. Brennan), and on a *Spirochæte* of unusual form (Mr. Cheshire).—Dr. Anthony read a paper on drawing prisms, on which a long and interesting discussion took place.—Mr. Dowdeswell read a paper on some appearances in the blood of vertebrate animals with reference to the occurrence of bacteria therein; Mr. Oxley, on *Protospongia pedicellata*, a new compound infusorian; and Mr. C. D. Ahrens on some new polarising prisms which he had devised.

Paris

Academy of Sciences, July 7.—M. Rolland, President, in the chair.—Remarks in connection with a note of M. Berthot on the mutual attraction and repulsion of the molecules of bodies, by M. de Saint-Venant.—Note on the absorption of chlorine by carbon, and on its combination with hydrogen, by MM. Berthelot and Guntz.—Remarks on the projected inland sea in North Africa, by M. de Lesseps. The author, who supports the scheme, replies to the objections raised by M. Cosson, and denies that its execution would involve the ruin of the Belad-al-Jerid and Sûf districts.—On the cholera epidemic, by M. E. Cosson. While admitting that the present epidemic in the south of France is of the Asiatic type, the author points out that it is of a much less virulent character than previous visitations. The germs of the malady seem to lose their intensity and power of transmission in proportion to the distance of the places whence they have been imported. They may thus be compared to the attenuated virus artificially cultivated by M. Pasteur. The efficacy of military cordons and measures of isolation and disinfection is insisted upon, and illustrated by reference to the results obtained by these precautions during the prevalence of cholera in Algeria in the year 1867.—On the so-called algebraic monothetic equations, in which all the coefficients are functions of a single matrix m, by Prof. Sylvester.—Memoir on the chemical composition and alimentary value of the various constituents of wheat, by M. Aimé. Contrary to the generally received opinion, the author concludes, from experiments made on himself, that whole meal or household bread, containing all the ingredients of the grain, is less wholesome and more indigestible than pure white bread made of the flour alone.—New researches on the structure of the brain and on the functions of the white fibres of the cerebral substance, by M. J. Luys.—On the developments bearing on the distance of two points, and on some properties of the spherical functions, by M. O. Callandreau.—Note on the holomorphous functions of any genus (mathematical analysis), by M. E. Cesaro.—On the determination of longitudes in the region of the Caucasus, letter addressed to M. Faye by General Stebnitski.—Note on the electric conductivity of highly diluted aqueous solutions of organic substances, such as ethylic alcohol, glycerine, phenol, glucose, urea, acetone, albumen, ordinary ether, and ethylic aldehyde, by M. E. Bouty. Researches on anhydrous phosphoric acid, by MM. P. Hautefeuille and A. Perrey.—On some new borotungstates, by M. D. Klein.—On the dishydrating action of salts, by M. D. Tommasi. According to the researches of M. Grimaux, salts would appear to favour the coagulation of colloidal substances by acting as dishydratants. But the author shows that in some cases certain salts produce the opposite result.—On perseite, a saccharine substance extracted from the berry of *Laurus persea*, and analogous to mannite, by MM. A. Muntz and V. Marcano.—On the bibromide of metaxylene, metaxylenic glycol, and other derivatives of metaxylene, by M. A. Colson.—Polarimetric researches on the regenerated cellulose of pyroxylenes and on the cellulose subjected to the action of sulphuric acid, by M. A. Levallois.—Experiments on the artificial fabrication of farmyard manure, by M. P. P. Dehérain.—Contribution to the comparative anatomy of the races of mankind: dissection of a Bosjesman, by M. L. Testut. These studies, made on a subject from twelve to fourteen years old, have revealed a muscular system in a more or less rudimentary state, which exists in a normal condition in various anthropoid and other apes, and in some instances even in mammals of other orders. In his remarks on the paper M. de Quatrefages points out that it supplies no fresh argument in favour of man's descent from a simian prototype.—On the submaxillary of *Oligotoma saundersii*, *Œdipoda cinerascens*, *Gryllus domesticus*, and some other members of the locust family, by M. J. Chatin.—Researches on the transpiration of vegetables under the tropics, by M. V. Marcano.—On a new genus of fossil grain (*Gnetopsis elliptica*, *G. trigona*, and *G. hexagona*) from the Upper Carboniferous Measures, by MM. B. Renault and R. Zeiller.

THE CONSTRUCTION OF ORDNANCE

A Treatise on the Application of Wire to the Construction of Ordnance. By James Ackman Longridge, M.I.C.E. (London: Spon, 1884.)

ABOUT thirty years ago, during the raging of the Crimean war, special attention began to be directed towards the improvement of our artillery. The old Board of Ordnance was abolished. The manufacturing departments at Woolwich were put under the control of a newly created Minister of War. That able and high-minded officer, Colonel F. M. Eardley-Wilmot, R.A., was appointed Superintendent of the Gun Factories, July 1855. He commenced his work in a thoroughly sensible and practical manner, and pursued his inquiries for suitable materials for guns both at home and abroad. He was ready to adopt anything, new or old, provided it was of the right sort. Sir H. Bessemer has remarked: "My early progress was known to only a few scientific men, among whom was Colonel Eardley-Wilmot, R.A., who took great interest in the invention." But in the summer of 1859 it was decided to adopt the Armstrong breech-loading system, and in November 1859 Colonel Eardley-Wilmot was requested to resign his post at the Gun Factories, to make room for Mr. (now Sir W.) Armstrong.

The 12-pounder Armstrong breech-loading field-guns appear to have given satisfaction, and the authorities at once proceeded to manufacture 110-pounders on the same system without exercising due caution, as explained by General Peel in his letters to the *Times* about September 1868. For, he says, the following sums were voted "for the purchase and manufacture of warlike and miscellaneous stores:—

In 1860-61 ... ... £2,830,625; and
In 1861-62 ... ... £3,006,049

a great portion of which was for the 110-pounder Armstrong guns, which had been adopted into the service without any sufficient trial of them." Among other things, the vent-pieces failed, no matter of what material they were constructed. All the while the nation had to abide strictly by the terms of its bargain—it had adopted the gun, and it must take the consequences. We have never heard that any variation in the principle of the invention was tried with a view to relieve the gun of the excessive pressure at the breech. It was said that there was a contraction of the bore just before the seat of the shot, so that there could be little doubt that the whole of the quick-burning powder then in use would be converted into gas before the projectile moved forward any appreciable distance. Something must therefore yield, and that was generally the vent-piece. Before abandoning the system it would not have cost much to take some disabled gun and remove the chief part of the obstruction to the initial motion of the shot. But the 110-pounders had failed, and there was end of the system—according to the decision of its own friends. But it will be seen that at least one system employing lead-coated projectiles of about 300 lbs. in weight was made to succeed.

The authorities then turned their attention to *muzzle*-loaders, with which they were more successful. Although they now used studded shot, they were careful to avoid all needless obstruction to the *initial* motion of the shot by the use of an increasing twist in the rifling. Also the high initial tension of the powder gas would in this case find some relief from windage.

About the year 1869 the Prussian Government instituted a comparative trial between the English 9-inch muzzle-loading gun and the 9¼-inch breech-loading gun of Krupp. Different opinions have been expressed respecting the fairness with which this competition was conducted. But this much must be said in favour of the decision arrived at, that the Prussians seem to have abided by it, and that they have not come to England to purchase muzzle-loaders constructed on the iron coil system. The striking fact was that Krupp could construct breech-loading guns to fire 200 to 300 lb. lead-coated projectiles from a 9¼-inch breech-loading gun with safety, whereas the Woolwich breech-loading guns failed with similar shot of 110 lbs. with a bore of about 7 inches.

Since that time breech-loading has ceased to be looked upon as an impossibility. We even learn incidentally that we have ships armed with guns constructed on that system.

About 1865 the Committee on Explosives was appointed, who continued their labours throughout many years. We are not aware that details of their observations, made with the chronoscope and crusher gauges, were ever published *in extenso*. So long as this remains the case, the conclusions of the Committee can never be completely accepted. But so many contradictory observations have been published that we are compelled either to doubt the results given by the crusher gauge or to suppose that the forces developed by fired gunpowder are liable to great variation, even where the initial velocity of the shot is the same. Observations with the chronoscope we put aside as of no value in obtaining an accurate measure of the forces, which vary rapidly, and, acting upon a body at rest, generate a high velocity in a space of 10 or 20 feet. Observations of that kind are only valuable when the force affecting the motion changes by slow degrees.

Throughout all these changes the Woolwich system has been in the main the Armstrong system of coils of wrought iron for both breech- and muzzle-loading guns, while the recommendations of steel by Krupp and Whitworth have been set aside partly on the score of expense. But now there are indications that the Woolwich system of coiling is not considered to be quite satisfactory.

Mr. Longridge says:—"Since 1862 millions upon millions have been spent, and we are now told that we are on the eve of a new epoch of expenditure, that the great array of weapons which we have provided are no longer up to the mark, and millions upon millions must again be disbursed before the nation is properly armed" (p. 2).

This seems therefore to be a favourable opportunity for the official consideration of Mr. Longridge's system of applying wire to the construction of heavy ordnance. No other system allows of the tension being so nicely and so readily adjusted. Mr. Longridge appears to have been the first to advocate this system of constructing guns, for so early as 1860 he presented a paper on the subject to the Institution of Civil Engineers. When he first applied

to the Government, the objection to his proposals was their extreme novelty, but later on he was told that there was no novelty in the principle of his designs!

Mr. Longridge states the problem to be solved in the following satisfactory terms:—

"Suppose a coil of wire situated near to the inner tube of the gun. It is laid on under a certain tension, but its state is altered by each successive coil which comes over it, and when the gun is completed it is no longer in tension but in compression.

"There is in a finished gun a certain distance from the centre of the bore at which the wire is in a neutral state; it is neither in tension nor in compression. All the wires proceeding outwards from this point are in a state of tension varying, according to a definite law, according to the distance from the centre of the gun. All those proceeding inwards are in a state of compression, as is also the inner tube on which they are coiled.

"In a gun thus constructed the aggregate of all the tensions is exactly equal to that of the compressions whilst the gun is at rest, but when the strain of the explosion is brought into action the state of each wire is altered, all the compressions are reduced and eventually changed to tensions, and all the tensions increased; and, in a gun properly constructed, if the pressure inside were increased to the bursting point, every wire would be strained to its maximum tensile force, and would give way at the same time" (p. 15).

Afterwards Mr. Longridge gives elaborate calculations of the tension proper for each coil of wire.

The system of "chambering" large guns is now in use at Woolwich, Elswick, and Essen, but it appears most objectionable. We quite agree with Mr. Longridge, that "chambering is a poor and inefficient expedient for lengthening a gun at the cost of its durability." He found "that in the case of the 38-ton 12-inch gun the result of chambering out to 14 inches was to reduce the length of the charge from 27 to 20 inches . . . and that this would *cæteris paribus* increase the velocity of the shot about 7 or 8 feet per second" (p. 17). In such a case the mere chambering would give an increased longitudinal strain of nearly 820 tons in the chamber, allowing a pressure of 20 tons per square inch to the powder gas, while the tendency to burst the coil would be increased in the proportion 6 : 7, or nearly 17 per cent. The Committee on Explosives profess to have discovered a so-called "wave action" which may or may not exist in guns fired under the same conditions. And it is claimed for "chambering" that it (1) gives a higher initial velocity, and (2) prevents the abnormal very high local pressures induced by long cartridges. In the case mentioned by Mr. Longridge 7 inches was the gain in the space through which the powder gas propelled the shot. But the charge being in a more compact form, only 20 inches long, would probably explode more rapidly than it would in the bore 27 inches long, and consequently the powder gas propelling the shot at corresponding points in the bore would be greater with the chambering, and consequently in that case the initial velocity of the shot might be expected to be greater, especially with the increment of 7 inches in the useful length of the bore. But it is difficult to imagine in what way chambering could reduce the stress upon the gun. We have found by calculation what would be the lengths of the following guns, in order to allow the same internal volume:—

	ft.	in.
71-ton Krupp gun, chambered ..	32	10 long.
,, ,, unchambered ..	33	11
80-ton Woolwich, chambered ..	26	9
,, ,, unchambered ..	28	1
100-ton Armstrong, chambered ..	32	8
,, ,, unchambered	33	10

From this it appears that the saving in total length of gun due to chambering is not great.

The process seems to have been this. After much trouble guns were manufactured which with a uniform bore and slow-burning powder stood tolerably well. In order to obtain an increased initial velocity the gun was chambered and therefore weakened. Sir W. Armstrong says that the calculated strength of his 100-ton chambered gun, which failed, was "far in excess of what a normal pressure would demand." And then he goes on to state, March 1880, that "Nothing, in fact, wants investigation so much as this powder question" (*Proceedings* of the R.A. Institution, Woolwich, vol. xi. p. 197). If chambering is to be profitably used it appears that it will be necessary to adopt steel and abandon coiling—both wire and wrought iron.

As a uniform bore gives the strongest form of gun, it appears to be very desirable to obtain a slow-burning powder less bulky than that now in use. But if that be not possible, we would either slightly lengthen the gun or use a powder a very little more energetic than that now in use, and just sufficient to compensate for a want of chambering.

Mr. Longridge quotes the following remark of Messrs. Noble and Abel on air-spacing:—"In cases where there is a considerable air-space between the charge and the projectile, it has been found that the energy developed in the projectile is materially higher than that due to the expansion of the powder gases through the space traversed by the projectile, and the cause of this appears to us clear.

"When the charge is ignited at one end of the bore, and the ignited products have to travel a considerable distance before striking the projectile, these ignited products possess considerable energy, and a portion of this energy will be communicated to the projectile by direct impact" (p. 110).

Well may Mr. Longridge exclaim: "With all respect to these gentlemen, we are quite unable to accept this explanation." The explanation we have to offer is that when a moderate air-space is left there will be a delay in the initial motion of the shot, and consequently the explosion of the charge for every position of the shot will have proceeded further than if there had been no air-space, and consequently the pressure of the powder gas will on the whole be increased. But, on the other hand, there will be a slight loss of velocity, since the powder gas acts on the projectile through a slightly reduced length of bore corresponding to the air-space.

We have never made experiments on the pressure and action of fired gunpowder. But we hold that with "chambering" and "air-spacing," using the same powder, the gun must be distressed, if by these means any sensible addition of initial velocity of the shot is obtained.

Mr. Longridge appears with reason to recommend the

adoption of a uniform twist of rifling, now slow-burning powder is used. The increasing twist of rifling was very probably effective in saving the gun when quickly-exploding powder was employed. But the importance of an increasing twist of rifling decreases as the action of the powder gas is rendered more nearly uniform. If the pressure driving the projectile throughout could be made perfectly uniform, then a uniform twist would exert a constant force to produce rotation.

Mr. Longridge says:—"So long ago as 17th March, 1860, the then Secretary of State for War, in his speech on the Army Estimates, said that 'these experiments proved that they had been wrong in using powder of so quick a detonating nature for artillery practice, and especially for rifled cannon, which required a weaker and slower powder than in the other cases" (p. 113). And twenty-four years later, March 20, 1884, the Secretary to the Admiralty said: "The old breech-loader had been found to be of no more use than a muzzle-loader, and the Government had adopted a gun twice as long as the old form of breech-loader." It is not very clear what all this means, but it is plain that vast sums of money will be required to provide long guns. Twenty years ago it might have been determined what effect every additional foot in length of a gun had in imparting increased initial velocity and increased steadiness to projectiles; but something more than the "rule of thumb" would be required to accomplish this.

England has of late come to acknowledge the value of technical training, and has shown a readiness to take a lesson from Continental nations. Is it not natural to suppose that some training of this kind might be found useful in settling the proportions of our guns, and in other matters of the same kind?

We think that Mr. Longridge has made out his case, and that his system deserves a fair trial in comparison with other promising systems. It has already been deemed worthy of a partial trial at Elswick, in France, and America. Experimental guns on different promising systems might in the first case be constructed of small calibre, and adapted to fire the service projectiles. If these proved satisfactory, then proceed to construct larger guns, and finally let that system survive which was found best fitted for its purpose. F. B.

OUR BOOK SHELF

A History of British Birds. By the late William Yarrell, V.P.L.S., F.Z.S. Fourth Edition. Revised to the end of the second volume by Alfred Newton, M.A., F.R.S., continued by Howard Saunders, F.L.S., F.Z.S. Parts XXI.-XXIV., January to July, 1884. (London: Van Voorst.)

ALTHOUGH, as we have said in a former notice of this work, it was a great pity that Prof. Newton could not be induced to complete his revised edition of Yarrell's well-known "History of British Birds,"—a subject in which he is before all other living naturalists at home, there can be no doubt that the task has fallen into good hands. Mr. Howard Saunders has not only completed a volume in about the same space of time that the former editor took to issue a single number, but has performed his work in a style to which, we think, little exception will be taken. The aim of Yarrell's "History of British Birds," we suppose, is to be sufficiently popular to be understood by all well-educated people, and at the same time to be thoroughly correct in scientific matters, so far as they are involved. As to Mr. Saunders' numerous remarks upon points of synonymy and distribution being entirely free from error, we should be very sorry to guarantee anything of the sort. But as we turn over the pages of his recent numbers, very few exceptional statements seem to present themselves, and most of these relate to what are to a certain extent matters of opinion.

Having finished his *Limicolæ* in Part XXI., Mr. Howard Saunders naturally proceeds to the Gaviæ, a part of his subject with which he is, as we all know, very familiar. An author who has worked out the Laridæ of the whole world in a thoroughly conscientious manner, and made this group his special study, is above all others qualified to prepare a special account of the "British" species. Of these Mr. Saunders recognises thirty as admissible into the list, though it is more than probable that this already large number will be still increased by the arrival in future years of stray individuals belonging to other species of this essentially wandering tribe of birds.

Congratulating our author on the accomplishment of the first volume of his portion of this excellent work, we may venture to express a hope that he will bring the long-delayed fourth edition of "Yarrell's Birds" to a speedy and satisfactory conclusion.

Bulletin of the United States National Museum. No. 19. "Nomenclator Zoologicus." By Samuel H. Scudder. 8vo. (Washington, 1882-1884.)

MR. SCUDDER'S "Nomenclator Zoologicus," which has been issued as No. 19 of the *Bulletins* of the United States National Museum, is not of a generally attractive nature, but will be of great use to working zoologists. It consists of two parts: the first of these, or "Supplemental List," contains the names of genera in zoology established previous to 1884, which are either not recorded or erroneously given in the previously issued Nomenclators of Agassiz and Marschall. To each generic name is added a reference to the work in which it is to be found. The second portion of Mr. Scudder's volume, or "Universal Index," contains an alphabetical index of all the names included in the "Supplemental List," together with those given in the Nomenclators of Agassiz and Marschall, and in the Indices of the Zoological Records. This second, most important part, contains about 80,000 entries, and, if correctly drawn up, as we have no reason to doubt is the case, will enable a naturalist who has recourse to it to determine at a glance whether any particular name has been already employed in zoology or not. All working naturalists will at once acknowledge the value of such an index as this, and will join us in thanking Mr. Scudder for having produced it. Could Mr. Scudder's index be magnified into a "Lexicon Zoologicum," giving the references to all the 80,000 terms in a single volume, a still more meritorious and useful work would be the result. Until this shall have been accomplished, it will still be necessary for a naturalist to refer to half a dozen or more different works in order to ascertain where any particular generic term has been employed in zoology.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Krakatão

I FORWARD a letter recently received from a former pupil, Dr. Stanley M. Rendall, which gives so graphic a description of the

sea of pumice which resulted from the eruption of Krakatoa, that you may perhaps not be indisposed to print it in NATURE.

University of Edinburgh, July 17 WM. TURNER

71, Rue de Genève, Aix-les-Bains, June 24, 1884

DEAR PROFESSOR TURNER,—I have been so occupied since meeting you in Edinburgh that it has been impossible to send sooner notes of my trip to Java. The first intimation that I had of anything unusual having occurred was on our way out to Australia. Making our way north again after having done our "easting" in about 45° S., we were all much struck by the splendidly vivid sunsets, and by the distinct interval of time between the actual disappearance of the sun below the horizon and the appearance of the deep red or crimson glow. This phenomenon was more striking as we sailed north. On reaching Queensland we heard of the volcanic eruption in the Sunda Straits and received the explanation of the so-called "Krakatoa Sunsets." I left Newcastle, N.S.W., for Batavia in a steamer about November 10, 1883, *viâ* Cape Leeuwin, sailing up the west coast of Australia. We first came across distinct evidences of the eruption about 200 miles before we entered the Straits of Sunda, in small isolated pieces of pumice-stone, which became much more numerous and finally took the form of yellow patches constituted by morsels of pumice varying in size from a pea or even smaller up to a cocoa-nut, rarely larger. As we neared Krakatoa itself, these patches were certainly more numerous and larger in size, but still the actual amount of debris was small, much smaller than I had expected to find after the account I had heard from persons who had previously traversed the Straits. The yellow patches were few and far between, and composed chiefly of a coarse dust with here and there larger lumps amongst it. Krakatoa, formerly the most fertile of all the lovely isles which one passes, rose like a vast cinder, still smoking. Not a blade of grass or a leaf was to be seen, just a grayish seared-looking mass. A large portion of the island had disappeared, and I was told that over the sunken part 300-fathom soundings had been taken. Between the island and Batavia we passed a few more floating patches of pumice as above described. After about eight days at Batavia we steamed down the coast to different ports, Cheribon, Tegal, and Samarang, being on the whole about three weeks away from the time we left Batavia to our return there, which took place, so far as I can remember, on January 1. On nearing Batavia again we passed through large patches of pumice-stone, patches of several acres in extent, some of the lumps forming them being of large size, roughly speaking about as big as a cwt. sack of coals, and all sizes below that down to coarse dust. We anchored for the night just outside the port in clear water. Early in the morning one of the officers called me to look at an immense floe of pumice-stone that was bearing down upon the ship, and very soon we were entirely surrounded, and formed the centre of about, I should think, a square mile. Though covering a large surface, there was evidently no great depth of matter. One could pick it up by throwing a bucket or heavy pail into the mass, and a small steam launch easily made her way through it to our side. We left Batavia early in the morning, and passed through two or three such collections, all making their way in the same direction by the action of a current, as there was no wind, the sea being perfectly calm. When about thirty miles from Batavia, we met coming towards us an immense field, similar, except for its greater extent, to those already described. I could not tell you by any means exactly how large a surface it covered, but at one time could only just make out the edge we had entered it at with the naked eye, and could not see its termination in the opposite direction with the ship's glass, so that it was at least several miles in extent. Also the depth of the pumice-stone bed was very great, offering considerable resistance to the ship's progress, as shown by its diminished speed. An iron fire-bar thrown over the side rested on the surface of the mass, instead of sinking. Large trunks of trees were not floating in the water, but resting on the surface of the pumice. The passage of our vessel left a wake of only a few feet, which speedily closed in again, so that to see it at all I had to lean over the stern and look under it as it were. It seemed exactly as if we were steaming through dry land, the ship acting as a plough, turning up on each side of her a large mound of pumice, especially noticeable on looking over the bows. Our passage through this made no great noise—just a soft sort of crushing sound. The effect was very striking and queer. I only regret that I did not time our passage through this, the largest mass we met. We passed through one more but smaller field in the Straits of Sunda, and after that do not remember again meeting with any even small patches of pumice-stone. I thought it curious meeting such immense quantities of the debris in the same place where, a month or five weeks earlier, only a few scanty, isolated patches existed. It was not due to a new eruption, so must be accounted for by the currents massing together a large number of scattered patches; or perhaps a certain amount had first sunk, and then, later on, had risen to the surface. I hope these short notes may be what you want; if I can give you any more information, I shall be delighted to do so.

With kindest regards,

Believe me yours sincerely,

STANLEY M. RENDALL

The Laws of Volume and Specific Heat

THE former, known as the "law of Avogadro," implies that any given volume at the same temperature and pressure must contain the same number of molecules. It includes the law of Chasles, viz. equal expansibility for equal increments of heat; and the law of Boyle or Marriotte, that the volume of any gas must vary inversely as the pressure.

The other is that of Dulong and Pettit; and as the former necessitated equal volumes, so this latter implies constant heats for parallel conditions. But, finding that few elements approximated this law, it was an early device to double, treble, or quadruple the old atomic weights to secure a supposed uniformity; and thus the law found this expression, viz. that the specific heat of any solid element would prove to be a measure of its atomic quantity.

This, put in plausible fashion, will be the stock instruction of the superficial books for some time to come; but in the higher circles of chemical life it is being admitted more and more that a great change has come over the spirit of this dream. Departures from the normal 6·4 are no longer attributed to errors of observation, and that constant is replaced by a range of 5·5 to 6·9; while, to keep within this, M. Weber has proved that the doubled carbon equivalent must be tested at a range of temperature exceeding 1000° C. He has found that within the limits of − 50° and 600° its heat value increases sevenfold! Well indeed may he say, "The idea that temperature can be overlooked must no longer be entertained;" also, "That the specific heats are not generally expressed by constant numbers; the physical condition of the elements influence their specific heats as much as their chemical nature."

These be great admissions from one of the highest authority, but they are as nothing compared with the new demands of physical chemistry. Mr. J. T. Sprague, an able and determined new chemist, has been the first in England to challenge attention to the recent researches of M. Berthelot, L. Troost, and others of the very highest chemical authority.

In a recent paper he admits that the new results "strike at the root of the most favourite chemical doctrines of the day, doctrines which are the foundation of the modern atomic weight and molecular theory, and consequently of the doctrines of atomicity, and the complicated molecular theories which have been based upon the supposed atomicity and specific bonds of different atoms."

The laws of Avogadro and Dulong and Pettit are offshoots of one principle, and one really implies the other. *If* true, it would follow that the atomic heat must be the same for all substances, or, if otherwise, the same quantity of heat would not produce equal expansions; also that the specific heats must be equal at all temperatures, or equal quantities of heat would act differently at different temperatures, or else it must vary equally for all gases, or they would expand unequally for equal quantities of heat.

Now it is a misfortune for these laws that none of these conditions subsist over wide areas. As a consequence of the two laws, an air thermometer should measure all temperatures by equal rates of expansion, and a given expansion should correspond to a fixed quantity of heat; such a thermometer should also read equally if filled with any other perfect gas.

In other words, these laws can only be true if the relation between the weight and volume of different gases be constant, and if the heat absorbed in producing a given change of volume is equal at all temperatures; that is, if the specific heat is constant.

These conditions are practically fulfilled by air, O, N, and H, between 0° and 200° C., so that the scale of temperature derived from the change of volume is the same as the scale derived from quantities of heat; but between 200° and 4500° there is a gradual growth of changed conditions which proves fatal to both laws,

and there is apparently an absorption of energy which does not appear either in the form of expansion or of sensible heat as temperature. At this high stage the specific heat of some of the simple gases has increased threefold, while some gases have a greater rate of expansion than others.

The same thing occurs with other simple gases, but at a much lower temperature, as, even within 0° and 200°, where dissociation cannot be entertained, chlorine and other halogens differ considerably from N or H, and at 1600°, if an air thermometer indicated 1600° for a given expansion, a chlorine one would register by expansion 2400° for an equal temperature, though with a much greater absorption of heat by the chlorine.

This difference is dependent on the fact that at 1600° the comparative density of chlorine has diminished one-third; or, in other words, that its volume, as compared with H, instead of being 1, has become 1·5; or, to put it in another way, that under these conditions, the specific heat of Cl is threefold that of H.

Quite apart from these extreme cases the specific heat is never a constant value; it takes more heat to raise a given weight of substance 1° at one temperature than another.

The specific heat increases with temperature, but differently for different substances:—

		0° to 100°		0° to 300°
Iron	=	·1098	...	·1218
Platinum	=	·0335	...	·0343
Mercury	=	·0330	...	·0350

The differences here are both distinct and small, but Be (glucinium) increases twofold within a moderate range, and we have seen that between − 50° and 600° carbon increases its specific heat sevenfold, or, as Mr. Sprague expresses it: "The heat relation of each substance is described by a particular curve; and the small differences observed in some cases are not errors, but actual differences of the several curves, and where there is approach to identity it is accidental, due to the temperature of observation being within a limit at which the curves are near their commencement, and have barely begun to separate."

However tempting or fashionable it may be to rush into hypothetic *explanations* of half-digested truths, yet I have taken some pains to keep within *facts*, which are in some respects incipient and but little understood.

If the causal differences in the production of light and sound had been fairly or patiently entertained, the "luminiferous ether" would never have been invented, which now crosses our path, as an "opaque fact, stopping the progress of further knowledge."

If a little more humility and patience had been evinced in respect of the expanding facts connected with gaseous volumes and specific heats, the old equivalents would never have been doubled, trebled, or quadrupled, to mar the symmetry of a beautiful science.

I quite agree with M. Troost, who, in repudiating the hasty references to dissociation, &c., observes: "The only consequences which *necessarily* flow from the experiments at high temperatures, or at low pressures, are that the coefficient of expansion is variable with the temperature, or that the coefficient of compressibility varies with the pressure." Also with the final conclusion of M. Berthelot: "The only law absolutely and universally applicable to the elements is the invariability of the relations of weight according to which they combine. This notion, and that of the energy brought into play in their reactions, are the sole and only firm foundations of chemical science."

SAMUEL E. PHILLIPS

A Carnivorous Plant

WITH reference to Prof. Moseley's letter in your issue of May 22 (p. 81) on "A Carnivorous Plant preying on Vertebrata," I may mention that in 1881, when surveying at the Paracel Islands in the South China Sea, I saw a somewhat similar occurrence. The tide was low on the reef on which I was strolling and admiring the lovely forms of coral existence. As I neared a pool cut off by the tide from the sea, I noticed amongst other submarine verdure a very ordinary-looking flesh-coloured weed about one foot high and of similar girth. My appearance alarmed numbers of tiny fish, which darted to the cover of overhanging ledges, but I noticed about half a dozen apparently seeking cover in the weed. Bending down closer, I saw that they were lying helpless about the fronds, with very little life left in them. Putting my hand down to pick up one of the half-dead fish, I found my fingers sucked by the weed, the fronds of which closed slightly on them. The fish were not caught by the head especially, but held anywhere round the body. The death seemed to be slow and lingering, and where the fish had been held its skin was macerated. These captives may have been caught some time, and were in different stages of exhaustion. I regret being unable to name the plant, or the young fish. They were from an inch to an inch and a half long. The plant had a dirty and rather slimy look about it. ALFRED CARPENTER

H.M.S. *Myrmidon*, Suakim, Red Sea, June 24

Phosphorescence of the Jelly-Fish

THE conclusions arrived at by Mr. Verrill (NATURE, July 17, p. 281) cannot fail to be of interest to all who have ever speculated on the significance of the luminosity displayed by so many *Acalephæ*, *Medusæ*, and other marine organisms. When in the tropics, in 1875, very similar ideas occurred to me, and in an address on the phenomena of cyclical propagation delivered to the Essex Field Club on January 28, 1882, I ventured to put forward the following views, which, as the address is still in manuscript, I will beg permission to quote:—"It was in the Bay of Bengal, when on the Eclipse Expedition of 1875, that I first saw shoals of *Medusæ* in their full splendour. Speculating on the meaning of the vivid colours and brilliant phosphorescence of these creatures, I came to the conclusion that both these characters might be protective danger-signals of the same nature and fulfilling the same function as the bright colours of distasteful caterpillars according to Wallace's well-known theory, or the phosphorescence of the *Lampyridæ* acc·rding to Thomas Belt ('Naturalist in Nicaragua,' p. 320). The 'urticating' powers of the jelly-fish would certainly make them unpleasant, if not absolutely dangerous, to predatory fish, and their bright colours and luminosity at night may thus be true warning characters." R. MELDOLA

London, July 21

Fireball

RECORDED personal observations, such as that of Miss Annie E. Cocking (NATURE, p. 269) last week, must needs be so rare that every detail of them—especially where the description is clear and simple—is of weight and value. What strikes my own mind as of much interest in this one is that, as the strange and fateful visitant sank towards the carpet, "at this instant a peal of thunder crashed *over the house*—it was the very loudest the writer had ever heard." This would seem to show that, whatever the nature of the insulator which envelopes these floating Leyden jars, their connection is maintained unbroken with the cloud of origin until the moment of discharge; and that, whatever causes the "crash," a peal of thunder takes effect rather in the cloud than at the point of contact. This agrees also with the descent of a fireball in the sea at Margate, mentioned in to-day's papers, where the crash of thunder occurred while the ball was yet in sight. But it is still another question whether these floating globes, which only discharge themselves *on contact*, do not in some important respect differ in their nature from the commoner "fireball" discharged with the directness, if not all the speed, of a lightning flash out of a thundercloud. It is a question towards the solution of which only observations such as that for which we are indebted to Miss Cocking can materially help us. HENRY CECIL

Bregner, Bournemouth, July 21

Animal Intelligence

THE following instance of animal intelligence may interest some of your readers. While walking through the forest here the other day, I found a young jay upon the ground scarcely able to fly. As I stooped down to examine it I was somewhat startled by a swoop made at my head by the old birds, their wings actually touching my hat. Determined not to be driven away, I remained by the young bird, whereupon a succession of like swoops were made at my head; these I easily succeeded in parrying with my stick, although the old birds frequently came in different directions. After about a couple of minutes the old birds seem to have come to the conclusion that nothing could be achieved in this fashion, and one of them, flying to some little distance, kept calling to the younger one, who half hopped, half flew after her. I of course followed; and now occurred what seems to me a striking instance of animal sagacity. The pines here are covered with lichen and a long, hairy kind of moss,

which easily crumbles into dust. The cock bird perched himself on the tree over my head, and began pecking with wonderful rapidity at this lichen and moss, so that, the moment I looked up, a shower of fine dust fell on my face. As I followed the young bird, the old one followed me, got on a branch as close to my head as he could, and sent a shower of dust down upon me. I can scarcely doubt that the dust, like the previous swoops, was intended rather *to blind me* than to distract my attention. Have instances of like sagacity—*i.e.* the apparent knowledge of the organ of vision and the means of injuring it—been noticed in *jays* before? KARL PEARSON

Saig, Schwarzwald, July 14

Munro and Jamieson's Electrical Pocket-Book

As Mr. A. Gray's criticism of our "Pocket-Book" is chiefly confined to literal errors practically unavoidable in a work of the kind, we take the opportunity of stating that we have lately been correcting these for the second edition, which, we are happy to say, has already been called for.

J. MUNRO AND A. JAMIESON

I OBSERVE that in my article in the last number of NATURE the third sentence of the third paragraph of p. 263, beginning "In the particular case, &c.," should have the words "corrected for the heat of combination of copper oxide and sulphuric acid" inserted after the word "this." A. GRAY

Glasgow, July 21

THE GREELY EXPEDITION

SUCCESS has at last attended the efforts to rescue the expedition to Lady Franklin Bay under Lieut. Greely; but, alas, out of the twenty-five men who started three years ago nineteen have perished. The party had left their station, Fort Conger, in August last, but did not succeed in getting further south than Cape Sabine, in Ellesmere Land, at the entrance to Smith Sound, about 150 miles from Lady Franklin Bay, and some 300 or 400 miles from Upernivik, the nearest Danish station. It is easy now to say that it would have been much better for the expedition to have stayed on in their comparatively comfortable quarters at Discovery Bay; the chances are that they would all have survived, and probably all have been rescued this summer by the relief party in the *Bear* and the *Thetis*.

We may remind our readers that the Greely expedition was sent out by the Government of the United States as one of the series of International Arctic expeditions, the main purpose of which was to take regular observations, according to a preconcerted plan, on the meteorological and other physical conditions of the Polar area. As the Greely expedition had to go much further north than any of the others, it started a year earlier in order to be sure to reach its post in time and be able to begin observations not later than August 1882. It was thoroughly equipped, both with scientific apparatus and with the material for a comfortable life under unusually trying conditions. The provisions supplied could have easily been made to last until the present summer, and we know from letters from Lieut. Greely, written shortly after his arrival, that the region around Lady Franklin Bay, 81° 44′ N. lat., abounded in musk oxen. In the summer of 1882 strenuous efforts were made to reach the station, but with no success. Last year two vessels were sent out, but the state of the ice was such that one was completely crushed and the other was glad to escape southwards almost as soon as it had entered the threshold of the intricate channel that led to Fort Conger.

The expedition which has been so fortunate as to rescue the six survivors consisted of the United States ships *Bear* and *Thetis* and Her Majesty's ship *Alert*, which was presented to the United States Government for the purpose. The condition in which the few survivors were found is almost too harrowing to record; how very nearly too late the rescue party were is impressively shown by the fact that Lieut. Greely, surrounded by his prostrate companions, was reading the service for the dying. "The red syenite rock forming Cape Sabine," Sir George Nares tells us, "and the islands in the neighbourhood of Payer Harbour is sterile and barren to the last degree. During the three days we were detained there, although parties from the ships explored the whole of the immediate neighbourhood, very little animal life was seen." The end of the cape or peninsula is cut into by a bay in which are several islands—Brevoort, Payer, Stalknecht, &c. Here Sir George Nares in 1875 left 250 rations, which do not seem to have been discovered by the Greely party; and of the 50,000 lbs. of food buried for them by the rescuing parties Lieut. Greely succeeded in finding only 250 lbs.

For full details as to the work accomplished by the unfortunate expedition during its almost three years' stay in so high a latitude we must await the publication of the records. Happily all the records have been saved, and thus the gain to science is likely to be of unusual value. What are the hardships to be met with, and the aspects of nature to be witnessed in this remote latitude, we know something of already from the records of our own expedition ten years ago under Sir George Nares. But the present expedition, profiting by the experience of its predecessors, and working on a carefully prearranged plan, is likely enough to tell us much that we never dreamt of. While the main work of the party was to make regular observations in physical science, it is evident that they have taken advantage of their exceptional position to push back the limits of our ignorance of Arctic geography. The lowest temperature experienced is stated to have been 61° below zero F. We all remember the exciting narrative of the painful scramble of Commander Markham and his brave men over the "palæocrystic ice" in order to make the attempt at least to reach the Pole. After about sixty miles they had to return baffled, glad to escape with their lives. Markham and Parr and their men had, however, the satisfaction of having attained the highest latitude ever reached—83° 20′ 26″. Lieut. Lockwood, however, succeeded in getting some four or five miles (83° 24′) beyond Markham's farthest, and 19° to the east of the English route.

Lieut. Lockwood, unhappily among the dead, seems to have been one of the most active and enterprising members of the expedition. He followed Lady Franklin Bay in its continuation, Archer Fjord, ninety miles beyond Beatrix Bay, Nares's furthest, quite to the other side of Grinnell Land, which he found to be an island, separated by Archer Fjord from the land to the south, now named Arthur Land. This was confirmed by the view obtained from Mount Arthur, 5000 feet high, west of the Conger Mountains, which may possibly be the range named after the United States by Sir George Nares. This Grinnell Land seems in many ways to be an interesting region; there are evidently several peaks or mountain ranges reaching a height of 5000 feet. A considerable area both on the north and south shores is covered by an ice-cap 150 feet thick, while, so far as we can judge from the report, there is a belt of comparatively open country in the interior some sixty miles wide. Even so late as March last, when the members of the expedition were dying one by one on Cape Sabine, exploration was not neglected. From Mount Carey to the north-west of the cape Sergeant Long obtained an extensive observation in the direction of Hayes Sound, which showed him that the Sound extends twenty miles further to the west than is shown on Sir George Nares's chart.

On his journey northwards Lieut. Lockwood succeeded in reaching 7° further east than Lieut. Beaumont's furthest in 1875. From a height of 2000 feet he saw no land to the north or north-west of Greenland, but away to the north-east, in lat. 83° 35′, and long. 38° 82′,

he saw a cape which he named Robert Lincoln. These observations are interesting. They seem to show that to the north of the American coast the sea is comparatively landless; while to the north-east the archipelago which borders the north coast of Greenland probably extends for a long distance, perhaps to meet the north-west extension of Franz-Josef Land. Lieut. Greely himself passed the summer of 1882 in the interior of Grinnell Land, in the east of which his station was located. Here he discovered a lake, sixty miles by ten, which he named after General Hazen, the Chief of the Signal Service of the United States.

From all this it is evident that, besides carrying out their strictly scientific work, the geographical explorations of the Greely expedition have been very extensive. From Fort Conger they extended east and west over some 40° of longitude and northward over 3° of latitude. They have enabled us to give more precision on our maps to the north coast of Greenland, and to extend it to the east and north-east. Grinnell Land they have found is an island largely covered by a thick ice-cap with a great lake in the interior, and separated by a narrow channel or fjord from the newly-named Arthur Land to the south. The "palæocrystic ice" of the Nares expedition is a myth, and it is evident that the ice of any part of the Arctic area is for no two successive seasons the same. It must necessarily be continually on the move, piled up in some parts to "palæocrystic" dimensions, while in other parts the sea may be comparatively open. One point seems to us conclusively settled. It is evident from what we know of the present expedition, and of the attempts to rescue it, added to the experience of previous expeditions, that there is no way to the Pole by the Smith Sound route for either ships or sledges. What Lieut. Lockwood saw from his vantage-ground to the north-eastwards seems to us to show that the route by Franz-Josef Land is more hopeful than ever, and that, if another attempt is made to reach the Pole, the choice of a starting-point will probably lie between that land and the New Siberian Islands.

L'ABBÉ MOIGNO

FRANÇOIS NAPOLÉON MARIE MOIGNO, mathematician, physicist, linguist, and ecclesiastic, was born at Guéméné (Morbihan) on April 20, 1804; as he died on Sunday, the 13th instant, he is worthy of a place among the English mathematicians whose names figure in Prof. Sylvester's British Association Address (Exeter, 1869). He was descended from a good old Breton family. Moigno first studied at the Collège de Pontivy, then proceeded to the Jesuit seminary of St. Anne d'Auray. In 1822 he went to another house of the fathers at Montrouge, where he passed his novitiate. In addition to theology he studied with great enthusiasm both the physical and mathematical sciences; in these he made rapid progress, and in 1828 arrived at a new mode of getting the equation to the tangent plane to a surface. Leaving Paris in 1830 on account of the Revolution, he spent some time in Switzerland, and here turned his wonderful powers of memory to the acquisition of some eight new languages, at the same time perfecting his knowledge of Latin and Greek. In 1836 the Jesuits appointed him to the Mathematical Chair in their house in the rue des Postes, Paris. Here he published the first volume of his great work, "Leçons de Calcul differentiel et intégral," following the methods used by, and utilising published and unpublished papers of, Cauchy. As his Superior was opposed to his scientific work, Moigno broke with the order, and gave himself up to his favourite pursuits. Having in 1845 become scientific editor of *L'Époque*, he was sent on account of that journal on a visit to England, Germany, Belgium, and Holland, and furnished to its columns his observations on these countries. About 1850 he filled a similar post on the staffs of *La Presse* and *Le Pays*. In 1852 he became editor-in-chief of *Cosmos*, a weekly scientific review. His connection with this journal closed in 1862, and in 1863 he founded a new journal called *Les Mondes*.

From the above hasty sketch it will be seen how active Moigno was as a journalist. In 1864 he was made a Chevalier of the Legion of Honour. Moigno wrote a number of works bearing on the relation of science and religion. Of his other works we give a few titles:—The continuation of the "Leçons," noted above, the fourth volume containing a part on the Calculus of Variations (written in conjunction with M. Lindeloef, 1861). "Leçons de Mécanique analytique, redigées principalement d'après les Méthodes d'A. Cauchy et étendues aux Travaux les plus recents—Statique." To Liouville he contributed a "Note sur la Détermination du Nombre des Racines réelles ou imaginaires d'une Équation numérique comprises entre des Limites données: Théorèmes de Rolle, de Budan, ou de Fourier, de Descartes, de Sturm, et de Cauchy" (v. 1840), and on a like subject ("Caractère analytique simple et sûr auquel on reconnait que la Méthode de Newton est applicable") to the *Nouvelles Annales de Mathématiques* (x. 1851). But the great part of his writings, by which he is generally known, is physical. The Royal Society's Scientific Catalogue gives the titles of some twenty-five papers, which are concerned mostly with light, electricity, heat, and the solar spectrum; one title only we copy, "Navigation aérienne avec ou sans Ballon," from *Les Mondes*. The "Répertoire d'Optique moderne ou Analyse complète des Travaux modernes relatifs aux Phénomènes de la Lumière" (1847-1850) took him some years to write, and is a work of considerable importance. Another useful summary of results is the "Physique moléculaire, ses Conquêtes, ses Phénomènes, et ses Applications, résumés des travaux accomplis dans les vingt dernières années" (1868).

From his *actualités scientifiques* we single out here "Science Anglaise, son Bilan au mois d'Août, 1868:" this gives from the Norwich meeting of the British Association (Moigno was a Foreign Associate, but was not able to be present at the gathering) the Presidential and seven Vice-Presidential Addresses, and the evening discourses by Huxley and Odling. Dr. Hooker's address was not at all acceptable to Moigno, and he prefaces his translation (" pour effacer quelque peu le fâcheux vernis du positivisme de M. Hooker") with an article of his own, contravening the address of a Positivist Professor, Signor Govi, delivered at Turin.

It is in this last character of a translator of English scientific works (he translated also Père Secchi's work on the Sun) that Moigno did us Englishmen a great service: the following titles will prove this:—"Sur la Radiation" (Tyndall's Rede Lecture); "La Calorescence—Influence des Couleurs et de la Condition mécanique sur la Chaleur rayonnante" (Tyndall); "La Force et la Matière," and "La Force (Tyndall), avec une Appendice sur la Nature et la Constitution intime de la Matière" (by Moigno); "Analyse spectrale des Corps célestes" (Huggins); "Sur la Force de Combinaison des Atomes (Hoffmann), avec addition d'un Aperçu rapide de Philosophie chimique" (by Moigno); "Le Son" (Tyndall); "Six Leçons sur le Chaud et le Froid" (Tyndall). In 1852 appeared a second edition of the "Traité de Télégraphie électrique . . précédée d'un Exposé de la Télégraphie ancienne de Jour et de Nuit," with an atlas; in 1850 he had published his "Proclamation patriotique. Belle Invention française." This is a pamphlet on the invention of tubular bridges by M. J. Guyot. In 1861 he wrote another pamphlet entitled "Cotonisation du Lin," which treats of a practical substitute for cotton. From the titles of these last pamphlets, as well as from those of many of the preceding works,

it will be seen that Moigno's mind was of a very practical cast, and that he was not immersed in the consideration of theories to the neglect of what is more useful.

THE COMPOSITION OF OCEAN WATER[1]

I.

ALTHOUGH ostensibly a report on the composition of ocean water, this memoir includes in its 250 large quarto pages the record of a far more extensive research than the title implies. It contains a detailed account of seventy-seven complete analyses of sea water, largely accomplished by the use of new and specially invented methods, the record of several independent researches into purely theoretical matters, and a number of exhaustive experimental criticisms of methods employed in similar work by other chemists. Taken altogether, the Report reads like the account of a life-work, and it is wonderful how the immense amount of work described in it could possibly be accomplished in the six years which have elapsed since the return of the Expedition. The rapid completion of the work is in great measure due to Prof. Dittmar's custom of having all the routine determinations made by assistants under his immediate supervision, while he devoted himself specially to the invention and trial of new methods and the repetition of doubtful experiments. The gentlemen who assisted in the research, and whose services Prof. Dittmar is scrupulously careful in acknowledging, are Messrs. John M'Arthur, Robert Lennox, Thomas Barbour, W. G. Johnston, James M. Bowie, James B. M'Arthur, G. A. Darling, and Moses T. Buchanan.

What first strikes a chemical reader on looking through the volume is the essentially mathematical treatment of the whole subject. The value of the statistical method in discussing experimental results has been gradually realised by chemists, but it is questionable if it has ever been applied more fully or with more satisfactory effect than here. The first care in every case, after taking all possible precautions to insure the utmost attainable accuracy, was to ascertain the limiting values of the probable error of the analytical method, and for this purpose there were never less than two and frequently more than four determinations made of each constituent. The utmost pains has been taken to represent the numerical results in as many aspects as possible, in tables, in mathematical formulæ, and by means of curves.

It is only possible here to indicate the principal contents of the six chapters into which the memoir is divided. The consideration of Chapter II. "On the Salinity of Ocean Water," may be conveniently reserved for a subsequent article, where it will be taken up along with Mr. Buchanan's report on the specific gravity of ocean water, which forms Part II. of the volume.

Although sea water had been subjected to many analyses in the earlier part of the present century, the only research of permanent importance until very recently was that of Forchhammer, who analysed a great number of surface waters from all parts of the ocean in 1864. Prof. Dittmar avowedly took this research as a guide, and intended his work to be merely supplementary to it; but from the circumstances of the two chemists the later work tends rather to supersede than to supplement the earlier. Forchhammer dealt with surface water only, collected and brought home in corked bottles by seafaring men who, however willing to do their best, could not be altogether trusted to observe requisite precautions, while Dittmar was supplied with water from all depths of the ocean collected at exactly known positions under the constant supervision of Mr. Buchanan, who secured each sample as it was drawn in a carefully stoppered bottle. We must take into account also the greater delicacy of the balances, and the more perfect analytical methods which are now available. The following table quoted from p. 203 of the Report, shows the most recent numbers assigned to the components of ocean-water salts compared with those given by Forchhammer:—

	Per 100 parts of total salts.	Per 100 parts of halogen calculated as chlorine.	
	Dittmar	Dittmar	Forchhammer
Chlorine	55·292 ...	99·848	not determined
Bromine	0·1884 ...	0·3402	,,
Sulphuric acid (SO_3).	6·410	11·576	11·88
Carbonic acid (CO_2)..	0·152	0·2742	not determined
Lime (CaO)	1·676	3·026	2·93
Magnesia (MgO)	6·209	11·212	11·03
Potash (K_2O) ...	1·332	2·405	1·93
Soda (Na_2O)	41·234	74·462	not determined
(Basic oxygen equivalent to the halogens)	−12·493		
Total salts ...	100·000 ...	180·584 ...	181·1

More than thirty elements are known to exist in solution in the ocean, but most of these are present in such minute quantity that it was hopeless to attempt to determine them in a number of small samples. Attention was accordingly confined to the chlorine, sulphuric acid, soda, potash, lime, and magnesia, which were estimated with very great accuracy and always by the same method, so that if more exact processes should be discovered at any future time the error of the method used may be calculated once for all, and applied as a correction to each analysis.

This rule of rigid adherence to one system was broken through in one case, that of the potash, where the ordinary process, which was first adopted, proved so unsatisfactory that it was worse than useless to continue to employ it, and the later analyses were conducted by a modification of Finkener's method that gave better results, through a curious balancing of the errors.

For the particular methods employed in each case it is necessary to refer to the memoir itself, where they are described with the utmost detail; but reference must be made to the great improvement which Prof. Dittmar has introduced in what was formerly called volumetric analysis, but which he now prefers to name *titrimetric*. It may be defined, somewhat paradoxically perhaps, as volumetric analysis by weight. The standard solutions are made up as usual by weighing the salt and measuring the water, but the whole solution is afterwards weighed, and its strength is thus determined with great accuracy. A balance combining strength and delicacy to an unusual degree is of course necessary for this purpose. By performing the titration in a weighed phial containing a weighed amount of liquid, and weighing it again after the reagent has been added to the proper amount, the burette error is obviated, except in those cases where the method of zig-zag titration is adopted, and then it only affects the measurements of the few drops of each reagent that are added in turn to produce and destroy the coloration which marks the end-point. All the chlorine determinations were made in this way by Volhard's method of precipitating the halogen by excess of silver nitrate, and estimating this excess by means of a standard solution of ammonium sulphocyanate in presence of iron alum.

The result of the seventy-seven complete analyses of ocean water, the description and discussion of which forms Chapter I., confirms Forchhammer's discovery that the percentage composition of the salts of sea water is the same in all parts of the ocean, and extends it to water from all *depths*. The application of the principle of constant composition to depth is subject to a slight but very important exception. The proportion of *lime* was found by Dittmar to be greater in very deep water than in that near the surface. Although the difference found exceeded

[1] "The Physics and Chemistry of the Voyage of H.M.S. *Challenger*. Vol. i. Part i. Report on the Composition of Ocean Water." By Prof. W. Dittmar, F.R.SS.L. and E.

the sum of all the probable errors of analysis, it was considered necessary to apply a more stringent test in order to make sure that the increase in lime was really in relation to the depth. For this purpose three mixtures were made, each of about seventy samples of water from all parts of the ocean, but the first consisting entirely of surface waters, the second of samples from between 300 and 1000 fathoms, and the third of waters from a greater depth. The exact analysis of these proved beyond question that the proportion of lime increases with the depth. The same bathymetrical mixtures were used for determining the bromine, as it, of all the minor components, is the one which might be supposed to vary most with the depth, owing to the fact of its being so largely absorbed by marine vegetation; but the proportion was found to be invariable within the limits of error. The details of this very difficult and interesting series of experiments occupy Chapter III.

The question of the amount of carbonic acid in sea water is one which cannot even yet be said to be definitely settled. The simple and elegant adaptation of Tornoe's modification of Berchert's and Classen's apparatus, which Prof. Dittmar made, and which is figured in the memoir, gets over the difficulty of determining the total carbonic acid in sea water; but unfortunately it had not been invented when the *Challenger* sailed. The daily determinations of carbonic acid in sea water which Mr. Buchanan made were performed by a method that only took account of what must be called, for lack of a better expression, the loosely-combined carbonic acid; that is, the portion of the gas existing in a state of absorption in the water, and the part combined with the normal carbonates to form bicarbonates. The immense number of determinations, made in the same way under exceptionally favourable conditions, form a valuable series for purposes of comparison, and Prof. Dittmar has not failed to utilise it. His critical experiments on Mr. Buchanan's method made with the view of ascertaining its limits of uncertainty were, he acknowledges, insufficient for the purpose. This is to be regretted, for an exhaustive series of carbonic acid determinations performed on the same water by the two forms of apparatus under favourable conditions might be expected to produce valuable results. Prof. Dittmar saw that it was useless to employ samples of *Challenger* water which had been kept for several years in order to estimate the total carbonic acid. But instead of giving up the research on this account he proceeded by an ingenious use of synthetic sea waters to study the behaviour of bicarbonates in solution. He says (p. 212):—

"I am aware that this part of my work lacks the degree of precision which would be desirable for my present train of reasoning. But I had not the time to embark in the far more elaborate investigation which would have been desirable. I have, however, quite lately resumed the matter on a new basis, and hope before long to be able to formulate the exact conditions of stability in sea-water bicarbonates as they exist when dissolved in real sea water, and amongst others to decide the question whether in this process they quite directly tend to become normal, and do not perhaps more directly gravitate towards the state of sesquicarbonate. In the meantime we must reason on what data we have."

And reasoning on these data he produces a most interesting theoretical disquisition on the dissociation-tension of dissolved bicarbonates at various temperatures, and shows how the ocean acts as the great regulator of atmospheric carbonic acid. The three main results of the *Challenger* observations on this subject are given (p. 220) as:—

"1. Free carbonic acid in sea waters is the exception. As a rule the carbonic acid is less than the proportion corresponding to bicarbonate.

"2. In surface waters the proportion of carbonic acid increases when the temperature falls, and *vice versâ*.

"3. Within equal ranges of temperature it seems to be lower in the surface water of the Pacific than it is in the surface water of the Atlantic Ocean."

In relation to Mr. Murray's theory of coral-reef formation and of oceanic deposits generally, it would appear probable that bottom waters contained more carbonic acid than those near the surface, and that this carbonic acid was the agent which dissolved the calcium carbonate of shells at great depths. Prof. Dittmar thinks otherwise. In his opinion Mr. Buchanan's numbers prove bottom water to contain no more carbonic acid than surface waters, and he supposes that the solution is effected by prolonged contact with the sea water itself, for by experiment he found that it was capable of dissolving calcium carbonate, though very slowly. It is not quite plain that Mr. Buchanan's numbers do warrant this conclusion, and there seems to be room for further research in this direction.

Chapter V. treats of the alkalinity of ocean water. The seventy-seven complete analyses showed that in sea-water salts there is a distinct preponderance of base over fixed acid, the difference being presumably due to carbonates; and the direct determination of the extra base by standard hydrochloric acid at the boiling point, after the method devised by the chemists of the Norwegian North Atlantic Expedition, brought out precisely the same result. The alkalinity of bottom waters was found to be distinctly greater than that of those from the surface, and this increase was exactly proportional to the larger quantity of lime present in the former. The alkalinity determinations give the only satisfactory measure of the carbonate of lime which exists as such dissolved in sea water.

The last and longest chapter is by no means the least important. It deals in a very exhaustive manner with the whole question of the absorption of oxygen and nitrogen by pure water, as well as by sea water. Finding that all previous determinations of the coefficients of absorption of these gases were more or less unsatisfactory, Prof. Dittmar entered on an elaborate series of experiments, which is fully detailed in the memoir, having as an aim the determination of the desired coefficients at different temperatures for both pure water and the water of the ocean. The second part of the research consisted of the exact analysis of the samples of air which had been extracted from sea water on the cruise by Mr. Buchanan, using Jacobsen's ingenious apparatus, which he has since simplified and improved.

There is an element of uncertainty about the extraction of gases which Prof. Dittmar scarcely seems to emphasise sufficiently. The water in every case was collected in one vessel and then transferred to another in which the gases were boiled out. The danger of atmospheric gases being absorbed was obviated in great measure by the precautions used; but if highly aërated water were brought up from a great depth some of the absorbed gases would be certain to escape during transference. The only remedy would appear to be the collection of the water in the gas-extraction flask itself, and there is no method as yet by which this can be done.

Prof. Dittmar and Mr. Lennox constructed a modification of Doyère's apparatus for the analysis of gases, which was found to work well. It is described and figured in the memoir. The results of the analyses are discussed in the light of the coefficients of absorption found in the earlier part of the research. The amount of air which ought theoretically to be absorbed by sea water of the temperature and at the pressure at which each sample was collected was first calculated, and then, from the actual amount of nitrogen found, the quantity of oxygen which should be associated with it was arrived at. The quantities of air found in solution were usually in defect of calculation, as might be expected when it is recollected that the water of the ocean is always in motion, the temperature and pressure to which it is exposed being very

different at different places; and the fact that absorptiometric exchange had not gone far enough to reproduce equilibrium would account for the few cases in which the dissolved gases exceeded the amount calculated. The interpretation of his results seemed unsatisfactory to Prof. Dittmar. He says (p. 182):—

"I am sorry to have to confess that I have not been as successful as I should have wished in drawing general conclusions from my numbers, and if I here reproduce my endeavours in this direction, I do so chiefly in the hope that some other person, having more experience than I in dealing with statistics, may take up the problem after me, and perhaps be able to extract the latent propositions which are therein concealed. In the tables which I propose to give, he will find all the data arranged in the most convenient form, so that all he needs is at hand."

The problem of the dissolved gases is very difficult when deep waters are considered. The method pursued by Dittmar was to find the amount of nitrogen absorbed, and to calculate the temperature at which that quantity would be taken up by water at the surface; then to find the corresponding amount of oxygen, and compare that with what was found by experiment. It is evident that if the ocean were stagnant in any part the processes of oxidation always going on would tend to reduce the amount of absorbed oxygen finally to nothing, while the amount of dissolved nitrogen would be unaltered, unless it were slightly increased by the decomposition of animal matter. In many cases the oxygen deficit was found to assume very large dimensions, though oxygen was never wholly absent from the dissolved gases.

Part I. of the volume closes with a summary of the chemical work, a note by Mr. Buchanan on the determination of carbonic acid, and an appendix describing some analytical methods. The summary contains a number of valuable suggestions for future work. These are divided under two heads, the first comprising such observations of water density and rough volumetric determinations of the alkalinity as can be carried on by any intelligent seafaring man after a little instruction. The second head includes work requiring the services of a skilled chemist for its accomplishment. It embraces further researches on the composition of ocean salts by determining with the utmost precision the amounts of the principal constituents for one particular station in the ocean, water from which could be collected in large quantity at various seasons; then it could be compared with water taken at various seasons from a widely distant station, and thus the interesting question as to whether there is *any* difference in the proportion of the salts in different oceans could be settled. The minor constituents should also be estimated if possible, and very particular attention ought to be paid to alkalinity and carbonic acid determinations in freshly drawn samples. Prof. Dittmar concludes with this significant suggestion:—

"Meanwhile the best thing that could be done in regard to all the analytical problems referred to would be to work many times on samples of the same kind of water, with a view of improving on the methods and ascertaining the extent to which that one water fluctuates in its composition."

The only way in which this can be done properly is in a laboratory on shore situated within easy reach of an abundant supply of sea water, and the support of such laboratories ought to be a leading feature in the marine stations several of which, it is to be hoped, will soon be in working order on our coasts. A beginning has already been made at the Scottish Marine Station at Granton, where the special chemical problem under investigation is estuary water. The *Challenger* results may be regarded as final, for the present at least, for ocean water proper, and the results of the German and Norwegian North Atlantic Expeditions have put the waters of partially inclosed seas on a permanent basis; but the study of estuary water has been almost neglected. This is the more regrettable because of the practical importance of a correct knowledge of the conditions of the water of an estuary, on account of its bearing on the migration of fishes into firths and up tidal rivers.

There could be no better field than the estuaries of the British coast for carrying out Prof. Dittmar's suggestion of continuous work on one kind of sea water with a view to the perfecting of analytical methods; and the perfecting of analytical methods, important though it be, may safely be predicted to be one of the least valuable results of such researches.

HUGH ROBERT MILL

ORNITHOLOGICAL NOTES

SEVERAL new magazines have made their appearance during the present year, the most important of them being undoubtedly the *Auk*, which is the name proposed for the journal of the American Ornithologists' Union, and which is to represent in America our old friend the *Ibis* of this country. The *Auk* is in fact a continuation of the *Bulletin* of the Nuttall Ornithological Club, and the general style of the work is the same. The papers seem to be interesting enough, but what strikes us as being decidedly above the average is the quality of the reviewing, which is developing into an art with our American brethren. Mr. Cory describes some new species of birds from Santo Domingo, the plate which accompanies his paper being scarcely up to the level of American illustration. Mr. Barrows continues his useful papers on the birds of Uruguay, and Prof. Merriam criticises Dr. Coues' "Check List," calling forth a sharp rejoinder from the last-named author in an article called "Ornithophilologicalities." In No. 2 many of the above-named papers are further continued along with others by Dr. Stejneger, who advocates some startling changes in ornithological nomenclature, and who also writes a useful paper on the genus Acanthis. Altogether, although the American ornithologists have elected to name their quarterly journal after a bird whose powers of flight were small, the excellence of the two numbers which have appeared reminds us of the perfection of that bird's powers of swimming and diving, so that they have taken as their symbol a species of lusty prowess which argues well for a continuation of the life and enterprise which is visible in the new magazine. We do not forget also that the Auk was a species common to Great Britain and North America, and therefore the very title is suggestive of a bond of union between British and American ornithologists which is certain to be strengthened with each succeeding year.

We have also received No. 1 of the *Bulletin* of the Ridgway Ornithological Club, which has been started in Chicago, and is named after Mr. Robert Ridgway, the well-known Curator of the Ornithological Department in the United States National Museum. The secretary of the new club is Mr. H. K. Coale, who is well known as a zealous and painstaking ornithologist, and under whose auspices there is doubtless a useful future before the infant society which he represents. The first number of the *Bulletin* contains only a single paper by Messrs. W. W. Cook and Otto Widmann, entitled "Bird Migration in the Mississippi Valley."

Mr. J. H. Gurney has just issued a "List of the Diurnal Birds of Prey, with References and Annotations; also a Record of Specimens preserved in the Norfolk and Norwich Museum," consisting of 187 pages. The *raison d'être* of this most useful work consisted in the publication of the first volume of the "Catalogue of Birds in the British Museum," by Mr. R. Bowdler Sharpe. The Norwich Museum, as is well known, contains one of the finest series of birds of prey in the world, and it will always be an imperishable monument to that true and self-sacrificing naturalist, Mr. J. H.

Gurney, through whose instrumentality this splendid collection has been brought together. The author commenced in 1875 an elaborate review of Mr. Sharpe's volume, giving a vast amount of additional information, principally founded upon the series of *Raptores* contained in the Norwich Museum. The complete list of the birds of prey which Mr. Gurney has now published contains an exact reference to these numerous critical papers in Mr. Sharpe's volume, but adds some of the principal synonyms, and gives the number of specimens contained in the Norwich Museum. The publication of this volume is certain to have one effect, which will take the form with all ornithologists of a hope that Mr. Gurney may feel able to continue his "Catalogue of the Raptorial Birds in the Norwich Museum," of which one part appeared some years ago; as it is certain that everything that emanates from his pen will be received with the greatest respect by his brother ornithologists, who have so long looked up to him as the greatest authority on the birds of prey.

UTRICULARIA VULGARIS

IT was proved many years ago that several of the aquatic and terrestrial plants distributed over various quarters of the globe preyed upon flies, larvæ, worms, crustaceans, and other species of small invertebrates.

For the greater part of the knowledge we have already received on this head we are indebted to the researches and experiments of Mr. Darwin, and I would refer any of my readers who may feel interested in the subject to his "Insectivorous Plants."

But until a few weeks since, when it was discovered by myself, and noted in NATURE by Prof. Moseley, that the bladder traps of the *Utricularia vulgaris* (Fig. 1) caught and destroyed newly-hatched fish, it was unknown that any of the recognised carnivorous plants possessed the power of also entrapping vertebrate animals, no single instance of the kind having been recorded by previous observers; yet it might at once have been naturally inferred, that, provided the experiment was made with creatures of a strength and size proportionate to the capacity of the organs of capture belonging to the plant, their action in every case would be precisely the same on either vertebrates or invertebrates. The *Utricularia vulgaris*, together with several other members of the same family bearing the generic name of Utricularia, and the specific, *neglecta*, *major*, *minor*, and *clandestina*, are very local in their habitat, growing in isolated patches in ponds and sluggish ditches, the type of place invariably selected by coarse fish to deposit their ova. This at once constitutes it as great an enemy to the small fry as the water-fowl and otters are to the larger fish in the streams, because for a considerable period after they emerge from the egg the young fish remain in the shallow water, and during this time innumerable quantities must be killed by the vesicles of the Utricularia.

Since I have been acquainted with the plant, I have noticed several peculiar circumstances in connection with it, which appear to have been entirely overlooked by all the botanical writers whose works I have consulted.

In the first place I have never seen it growing, unless displaced by the action of the wind, except on the darkest and shadiest side of the pond from whence I obtain my specimens, and then it is almost invariably hidden beneath other aquatic vegetation, as if its deeds caused it to shun the light. It also exhibits the same tendency to avoid particular spots which frequently is evinced by snakes in selecting only one side of a field or part of a hedge to the entire exclusion of the remainder, and by fish in choosing the dirtiest and most unlikely ditches as a spawning bed in preference to those which are cleaner and apparently in every respect better suited to the purpose.

I am of opinion that an excess of light is prejudicial to the plant, because, if when kept in an aquarium it is exposed to the full glare of the daylight, the valves appear to lose their elasticity, and the vesicles become detached from the stem, and drop off.

Another predominating cause for this strange habit of growing in only one or two spots may perhaps be ascribed to this, that wherever I find the Utricularia there is always a luxuriant mass of Confervæ around it which harbours numberless insects, and, having no roots at any time of its life, is entirely dependent upon its vesicles for its sustenance; hence it only flourishes where prey is plentiful.

In confinement it is impossible to keep it in a healthy state unless the glass is darkened; and as nearly as possible its artificial condition is assimilated to its natural one. Where young fish are kept, it is anything but a desirable inmate of the vessel in which they are confined. One eminent piscicultural authority states that he had several

FIG. 1.

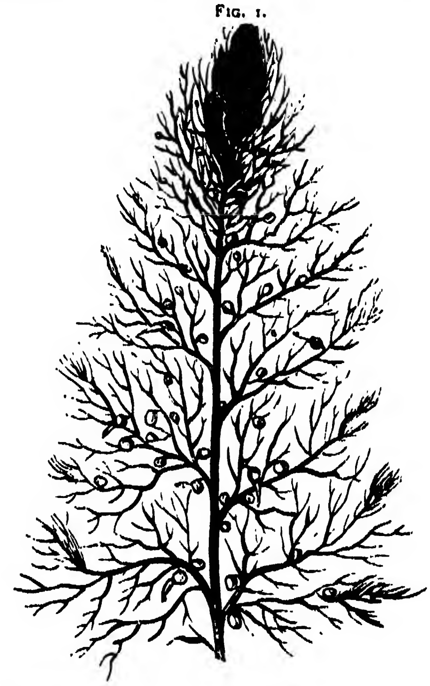

FIG. 3.

FIG. 2.

plants in his aquarium with some young axolotls, and he noticed that the small salamanders gradually disappeared; now he can give a very good guess where they went to.

My friend Mr. Kelson, who has recently had charge of my aquariums during my absence from home, agrees with me that the foliage possesses some poisonous properties detrimental to fish. Whether it does so or not I hesitate to assert, but all I know is that out of a batch of young roach placed with some freshly-gathered *Utricularia*, many of them in a little while lay dead on the branches.

With regard to its method of catching insects or anything upon which it preys, I believe that the processes are armed with tiny spines similar to the recurved teeth of a pike, or the serrations of an awn of barley, and these utilise the struggles of the creature caught to push it further on but prevent its return.

When a fish once touches one of the processes, whether

by the head (Fig. 2) or by the tail (Fig. 3), the result is precisely the same, it can never escape; and so tenacious is the grip with which it is held, that I have only once observed an insect get away after being caught. Otherwise I cannot conceive how, without some such arrangement, if the processes were perfectly smooth, they could retain anything so delicate even as the body of a young fish, much less would they be able to hold the larger creatures. I am the more inclined to this view because, when a fish emerges from the egg it is nothing but a transparent line of light, a substance without a substance, into which the most microscopically minute projection would enter without difficulty; and when it is borne in mind how easily the hair-like sting of the common nettle can penetrate the human cutis, taking into consideration the relative thicknesses of the two, I am satisfied that my argument, though open to contradiction, has at least the beauty of possessing some slight amount of probability.

I was hoping that before this I should have been in possession of several more facts concerning the *Utricularia* and its power of killing fish in a state of nature, but, unfortunately, at the time I was preparing for my observations I suffered from a severe attack of illness, which for this season at least has incapacitated me from carrying out my intentions; but I hope in the ensuing one to lay bare a few more facts concerning this new and novel enemy of the pisciculturist. G. E. SIMMS, JUN.

KANSAS

THE authorities that govern the individual States and Territories of America show themselves well-advised when they set to work to investigate the natural history and resources of their respective possessions in a healthy and unbiased spirit, and nothing is more calculated to give confidence in the future of the State than the knowledge that the truth, the whole truth, and nothing but the truth has been presented to all who are interested, with the indorsement of well-known scientific experts. The State of Kansas, which not many years back was so exercised and torn to pieces with internecine quarels and fillibustering forays, as to obtain the dolorous name of "bleeding Kansas," now appears before the world in very different guise—no longer bleeding, but with its wounds staunched; not restless, but peaceful, and bent on carrying out to the utmost the programme of wealth and prosperity which a careful examination of its capabilities shows us to be not only possible but assured.

The Third Biennial Report of the State Board of Agriculture is a portly volume of great value in many ways, although those points that deal with the geology and natural history will of course offer the most interest to the readers of NATURE.

From the geological sketch given by Mr. O. St. John we learn that Kansas, a parallelogram in shape, and containing no less than 80,000 square miles or 52,531,200 acres, lies wholly within the prairie region that intervenes between the Rocky Mountains and the Missouri; and although, to the ordinary observer, it appears to be an exceedingly flat region (Kansas City has only an elevation of 751 feet above the sea), there is, in reality, a gradual and regular ascent of the surface to the north-west corner, where the land assumes a maximum height of 4000 feet. What configurative irregularities there are, are principally due to erosion, as there is a remarkable absence of any geological displacement sufficient to produce mountainous folds, and thus give origin to local drainage systems. The most salient features of the landscape are bluffs (seldom above 500 feet in altitude), though in the larger valleys they are sometimes precipitous and intersected by ravines. The prevailing characteristic, however, is that of grassy uplands in billowy stretches, the drainage being provided for by numberless narrow channels called "draws." The general drainage system is easterly, and pretty well divided between the Missouri and Arkansas basins. The northernmost half of the State is watered and drained by the Kansas River, with its tributaries, the Delaware or Grasshopper, Blue, Solomon, Republican, and Saline on the north, and the Smoky Hill on the south; and these, with a small area drained by the head waters of the Osage River, all form part of the Missouri system. The basin of the Arkansas is met with a little to the south of the Smoky Hill, the river itself having a general south-east course into the Indian territory. The volume of the Arkansas from its distant source in the Rocky Mountains far exceeds that of the Kansas, though its valley is very little deeper, nor has it such important tributaries as the latter river. About the centre of the State, the Arkansas makes a considerable bend, receiving previously the Walnut and Pawnee Rivers, while east of the bend are the upper valleys of the Neosho, Verdigris, White-water, Little Arkansas, and Cimarron, though, as a matter of fact, nearly all these streams effect their junction with the Arkansas outside Kansas, and in the Indian Territory. The Neosho is locally famous for its valuable water power and its rich agricultural valley, and the Cimarron for its deeply eroded bed and the variegated sculptured strata of its cañon walls. The two typical rivers of Kansas State are therefore the Kansas, its valley consisting of a wide belt of low-terraced alluvial land, of great fertility, bounded by beautiful slopes terminating in frequent rocky bluffs, and the Arkansas with its magnificent reaches of level bottom land, whose depth of soil is composed of travelled sediments brought from the mountains and plains lying to the westward. Here and there the border uplands encroach upon the valley, showing shelly limestone strata, and deep, irondyed sandstone ledges.

The geology of Kansas is of a simple nature, and almost entirely composed of three principal formations, the Carboniferous, Cretaceous, and Tertiary. The Palæozoic rocks, as represented by the Carboniferous, appear at the surface over an area of about one-third of the entire extent of the State, entering it from the south-east, and eventually passing beneath the Dakota sandstone, which is the line of demarcation between the Palæozoic and Mesozoic series. After the disappearance of the Carboniferous rocks underneath this sandstone, they are not seen again until the Rocky Mountains, where their upraised edges have been bared by denudation at the foot of the ranges. The lowest member of the Carboniferous (Lower), as seen in Kansas, is the Keokuk limestone, which occupies a small area of about forty square miles in the extreme south-east corner, and consists of bluish-gray siliceous limestone, interbedded with cherty layers above, and often associated with brecciated siliceous matter. Limited as the Keokuk area is, it is of exceeding value to the State, for it includes the ore district of lead and zinc, and has already brought a considerable population to the newly-founded towns of Empire and Galena, on the banks of the Short Creek, a tributary of the Arkansas. Not only has a busy mining district been here established, but, owing to the excellence and accessibility of the Cherokee Coal-measures, a little to the west, the ores are enabled to be speedily and cheaply reduced at the furnaces of Weir and Pittsburgh, a few miles to the north. Galena, the ordinary sulphuret of lead, furnishes almost all the ore of that metal, together with its derivatives, cerussite or carbonate of lead (the "dry bone" of the miners), and pyromorphite or phosphate of lead. As is usually the case, the lead carries a small percentage of silver, from one to one and a half ounces to the ton of ore. The zinc ores consist of the common blende or sulphuret, "black jack," calamine (hydrous silicate), smithsonite (carbonate), and zinc bloom, many of the ores being of great beauty, from their amber and garnet tints. Associated with the ores are chalcopyrite or copper pyrites, green carbonate of copper,

bisulphuret of iron or mundic, calcite or "glass-tiff," dolomite, quartz, and bitumen. The base rocks of the district consist of a deposit of limestone 100 feet in thickness, charged with characteristic Keokuk fossils, which, however, are much comminuted and splintered, and bear evidence of the pressure and tension to which the strata have been subjected. The Kansas ores are similar in almost all parts to those of the Missouri district, and it is considered quite possible that time will reveal the existence of other ore-bearing strata.

The large area of Upper Carboniferous series may be roughly divided into Upper and Lower Coal-measures, the latter occupying between 4000 or 5000 square miles, and passing, in the west, conformably beneath the Upper Measures. The series is largely made up of shales and sandstones, with occasional thin beds of limestone and iron ores, but its chief economic value consists in possessing workable beds of coal. These are mostly distributed in the lower 400 feet of strata, and are somewhat irregular and variable in thickness. Some of the coals indeed are found in little isolated basins or pockets, filling trough-like depressions surrounded by ledges of the older formation; but as a rule, the thinner coal-beds are remarkable for their persistence over a large extent of ground. The Cherokee coals are of a very superior quality, and they (together with most of the Kansas lower beds) contain less sulphur than the coals of either Illinois or Iowa. Naturally there is a great demand for coking purposes and local consumption, while pretty heavy shipments are made to the towns and cities on the Missouri River. These Lower Coal-measures also contain excellent building-stone and hydraulic limestone, which is extensively utilised for making cement. The general inclination of the strata is north of west, with a dip that seldom exceeds 10°. The estimate of the Lower Coals, from an aggregate thickness of four feet, is 20,000,000,000 tons, and if the area be extended to that occupied by the overlying Upper Measures, so as to reach the Lower Coals accessible from 500 to 1000 feet, the product may be fairly estimated at double.

The Upper Coal-measures have an aggregate vertical thickness of at least 2200 feet, the exposed area extending for 24,000 square miles; but in the character of the component strata they present a marked contrast to the Lower series, on account of the limestone ledges which form such striking features in the landscape. The lower beds are characterised by frequent and thick deposits of gray limestone, succeeded in the middle portion by darker, rusty, weathered ledges, and in the upper by light, buff-gray rock. The sandstones occur in some half-dozen well-developed horizons along the line of the Kansas valley, usually in the condition of arenaceous shales, and affording local supplies of building and flagging stones. In Osage County these have an additional interest, as being marked with casts and tracks of gigantic Batrachians. The limestone beds are somewhat deteriorated for building purposes by cherty deposits, but, on the other hand, they contain ironstone nodules of hæmatite and carbonate ores, with crystals of sulphate of lime and beds of massive gypsum, varying in thickness from five to fifteen feet. These gypsum deposits are capable of affording inexhaustible supplies, which are used most beneficially as manure for the soil. Where the cherty concretions are not met with, the limestone beds yield magnificent building-stone, the texture and colouring of which can be seen to great advantage in the State House of Topeka and many other public buildings. The Upper Coals are distinguished from the Lower by their more brittle texture and a larger percentage of ash and impurities. Though there are several valuable and persistent seams, such as the Blue Mound and Osage coals, thinness is a decided characteristic of the Upper Measures, few, if any, being above thirty inches, and the greater number not exceeding ten inches. But, although the Upper Measures are clearly of not so much economic importance as the Lower, it is quite possible to reach the Lower by tolerably deep borings through the Upper, and indeed this has been already successfully demonstrated.

The Mesozoic age in Kansas is represented solely by Cretaceous formations, which, however, occupy the largest area of any in the State, being no less than 40,000 square miles. The series is composed of three divisions, viz. the Dakota, Benton, and Niobrara, all belonging to well-recognised lower members of the Cretaceous rocks of the Upper Missouri region. The Dakota beds consist of sandstone interbedded with variegated shales, with occasional layers and pockets of impure coal. The sandstones are permeated and deeply stained with ferruginous matter, the iron being often concentrated around nuclei, forming singularly-shaped concretions. The proximity to the ancient land area is denoted by the rather extensive fossil flora usually found in these concretions, but the fauna is more limited in variety, comprising, so far, a few fishes, a large Saurian, and several species of Mollusks. The sandstones vary lithologically, but are usually compact and often intensely hard, forming highland ridges marked by rugged and picturesque features. Less is known of the Benton beds than of the other members of the series. They consist of argillaceous and calcareous shales, with thin layers of limestone, overlaid by dark-coloured shales, but good exposures of these rocks are rarely found. They have, however, yielded to the palæontologist several Saurians, while the limestones are frequently charged with fine ammonites, the shells of *Inoceramus*, the gigantic *Haploscapha*, and myriads of the little *Ostrea congesta*. The Niobrara beds are the most important of the Kansas Cretaceous formations, and offer much better-marked horizons. The lower portion shows alternations of fragmentary limestone and shales, which above pass into shelly limestone, and, in some localities, into chalky limestone. All these layers are charged with a wonderfully numerous and varied Vertebrate fauna, allied to forms which are common in the Colorado shales of the Rocky Mountain region, and consist of remains of Teliosts or common bony fishes, sharks, Saurians, and an extraordinary species of bird, whose jaws are armed with teeth. The mineralogist will also be interested in these beds, as furnishing beautiful examples of selenite crystal. From a landscape point of view, also, the Niobrara beds are instructive, as they are frequently intersected by miniature cañon labyrinths, and exhibit varieties of monumental forms detached by the erosion of the valleys, some of these, composed of a coping of limestone and a shaft of chalk and compact shale, rising from 20 to 70 feet in height. In an economic sense the Cretaceous series is of considerable value. The Dakota deposits contain three beds of lignite, the Benton shales yield quantities of septaria, used for making the finer qualities of cement, together with excellent chalk applicable for whiting, while the Niobrara beds furnish vast supplies of pure lime. All the divisions yield excellent building-stone, and throughout the formation a productive supply of salt occurs, from the brines of which there is already a brisk annual trade of 35,000 bushels.

The most recent formation of Kansas is principally in the north-west of the State, where there is a Kainozoic area of Pliocene beds of about 11,500 square miles, extending thence from Colorado and Nebraska, where a vast stretch of country is occupied by the White River formation. Its typical features are loosely-aggregated sands, more or less calcareous, forming irregular strata of brown and gray sandstone, while in some places siliceous beds occur, associated with several varieties of chalcedony, and containing fragments of the tusks of a very large mammal. The fauna is most interesting in this respect,—beaver, rhinoceros, camel, deer, wolf, and turtle being all represented. The district is noted for its eroded mounds and columns, the most striking being the Sheridan *Buttes*, which rise in perfect

isolation to 200 feet above the Smoky Hill River, the summit capped by a heavy ledge of light gray, very hard siliceous rock, which has been weathered into miniature grottoes in the higher of the two cones. Underlying the Pliocene beds is a thick deposit of chocolate-coloured shales, with concretionary masses of limestone and septaria, and splendid crystals of selenite. Among Post-Tertiary deposits, examples are to be found, in the eastern portion of the State, of the Drift and Loess, the latter being strikingly displayed in the bluffs that bound the Missouri River valley for so many hundreds of miles in the States of Iowa, Nebraska, Kansas, and Missouri.

An appendix to the foregoing geological account is added on the botany of Kansas, by Prof. J. H. Carruth, but it is very short, for the reason that the catalogue of Kansas plants was made in 1880, and the present notice is merely to record certain additions (about 36) to the 1430 plants already found, of which only 30 are non-flowering. Considering that New York, with its varied surface and qualities of soil, can only show 1450, it is most interesting to note that Kansas, with its comparatively uniform soil and surface, produces almost as many.

A valuable report on the Kansas entomology is given by Prof. Popenoe, who furnishes detailed accounts of certain insects that commit ravages upon the crops. Among these figure prominently the large poplar-borer (*Plectrodera scalator*), which is a great tree-destroyer, making innumerable holes in the trunks of the willow and cottonwood. A singular fact is recorded of the buck moth (*Hemileuca maia*), viz. that as a larva it possesses a peculiar means of defence. The coarse, black prickles with which the body is covered are very sharp, and when they penetrate the skin on the back of the hand or elsewhere, they produce little pustules and a sharp nettle-like sting, though not of any duration. The red-lined tree-bug (*Lygæus trivittatus*) is a relative of the well-known squash-bug, and does infinite damage to the elder-tree, besides evincing a strong partiality for the interiors of greenhouses, where it destroys geraniums, ipomeas, abutilons, and other horticulturists' pets. The chequered snout-beetle (*Aramigus tesselatus*) has usually been known to infest leguminous plants, and more especially the silver-leafed prairie pea (*Psoralia argophylla*). Latterly, however, it has been noticed to pay great attention to the sweet potato, and has inflicted considerable havoc on that crop. The harlequin cabbage-bug (*Strachia histrionica*) attacks the Cruciferæ, and especially the wild cress (*Lepidium*), mustard, radish, turnip, and cabbage. The abundant little beetle known as the corn-root worm (*Diabrotica longicornis*) has only recently been discovered to be a corn-pest of the first magnitude, attacking the roots about the period of "earing," and causing a partial development of the grains.

Though only the points that bear most on Kansas natural history have been noticed here, it should be stated that the volume gives an exhaustive account of the resources and statistics, commercial, social, and educational, of each county in the State, and that the whole is illustrated by an admirable series of maps.

G. PHILLIPS BEVAN

NOTES

THE death is announced of Ferdinand von Hochstetter, the German mineralogist and geologist, whose name is intimately associated with the geology of New Zealand. Hochstetter was born in Würtemberg in 1829. In 1857 he joined the *Novara* expedition, but quitted it at New Zealand, the geology of which he spent a considerable time in investigating. In 1860 he was appointed Professor of Mineralogy and Geology in the Polytechnic Institute of Vienna, and in 1867 was made President of the Vienna Geographical Society. Among his published works are: the "Topographico-Geological Atlas of New Zealand"; "Geology of New Zealand"; "Palæontology of New Zealand"; "The Geology of the *Novara* Expedition"; "Rotomahana and the Boiling Springs of New Zealand"; besides works on the geology of Eastern Turkey, the Ural, and various popular publications.

IN the name of fair criticism, in the interests of true science, and in defence of a man who has grown gray in the public service, and who has recently retired full of years and honour to the rest he so well merited, a protest should be made against the language in which the *Mining Journal* last week permits itself to speak of Mr. Robert Hunt, F.R.S. We do not choose to discuss the relative merits of the new "Mineral Statistics" and those with which his name is so familiarly conjoined. But by all who know how entirely Mr. Hunt's heart and soul were in his work at the Mining Record Office and how unwearied were his labours on its behalf, an emphatic and indignant repudiation will be made of the charge brought by the anonymous critic that he failed to do his duty and set a bad example to his subordinates. Mr. Hunt needs no defence from such an odious charge. We cannot but express our regret that it should have been made in the columns of a respectable journal and under cover of an anonymous review.

WE are still a long way from admitting that a little elementary physiological knowledge is a desirable element in general education. But it is not often that such a glaring example of the want of it is met with as is revealed by the following extract from a despatch of the Acting Consul at Panama recently presented to Parliament. It would not be easy to find its parallel among the worst answers in the May examinations of the Science and Art Department:—"Many essays have been written on this appalling scourge [yellow fever], its origin, and its existence, but nothing seems more probable, more reasonable to me, than comparing the human blood to milk, which under influence of temperature and circumstances becomes curdled. In the like manner, the human blood, the human frame and organism, under certain abnormal, adverse, and unfavourable circumstances, become curdled, and enter into a state of dissolution, more or less rapid; the blood, owing to its component parts, coagulates, being impregnated with bile, phosphate, and albumen, through the stagnation of the liver and kidneys. This my theory is the one I certainly believe in. *Savants* assert that the disease is generated by spores of the marine mushroom (*Mycenium fungi maris*), which multiply in thousands per minute. Others profess it to be animalculæ termed 'microbes.'"

MR. JOSEPH THOMSON, the leader of the Geographical Society's expedition to East Africa, has arrived in this country. Mr. Thomson has suffered greatly from the hardships which he had to endure, and it will be several weeks before he regains his usual vigour. Mr. Thomson's expedition has been completely successful, and he himself estimates the results as of far greater scientific importance than those of his first expedition. The region traversed by him, from Mombassa to the north of Victoria Nyanza, is entirely volcanic, and his observations therein will be of great geological interest. There is still one volcano, west of Kilimanjaro, which shows signs of activity. Mount Kenia, though covered with trees, stands amidst a desert. The Masai, the leading people of the region explored, are of special interest. Their features, customs, dwellings, religion, language, differ markedly from those of any other African people with whom Mr. Thomson is acquainted. Fortunately besides his copious notes he has brought home many photographs, so that his forthcoming narrative is sure to be of unusual interest and value.

THE Conference on Water Supply by the Society of Arts will be held at the Health Exhibition to-day and to-morrow. The Conference will meet each day at 11 a.m., and will sit till 1.30, then adjourn till 2, and sit again till 5. p.m. The papers and

discussions will be arranged under the following heads:—1. Sources of Supply. 2. Quality of Water; Filtration and Softening. 3. Methods of Distribution; modes of giving pressure, house fittings, discovery and prevention of waste, &c., &c. The proceedings will be continued on Friday, and if necessary on Saturday. The readers of papers will be restricted to twenty-five minutes. Speakers will be restricted to ten minutes. The papers to be read will, in most instances, be printed and distributed in the room.

LORD REAY has received additional names of foreign delegates to the International Conference on Education from Austria, Baden, Belgium, France, Netherlands, and Switzerland. Prussia and Denmark contribute reports on the state of education in those countries. Lord Carlingford will preside at the opening meeting on August 4, at 11 a.m.

AT the request of the Council of the British Association for the Advancement of Science, Admiral Sir Erasmus Ommanney, C.B., F.R.S., has consented to act as Treasurer during the meeting at Montreal, Canada. We learn that Prof. W. G. Adams of King's College will be unable to give the Friday evening lecture at Montreal, and that Prof. O. J. Lodge will take his place. The subject of Prof. Lodge's lecture will be "Dust." Prof. Bonney sails for Montreal to-day.

THE death is announced of the Swedish chemist, Prof. Sten Stenberg, born in 1825.

ACCORDING to a note contributed to a recent number of the *China Review* by M. A. Fauvel of Hankow, the Foreign Office and the authorities at Kew are anxious to know the name of the tree from which the well-known tea-chests are manufactured. The Chinese name is of little use for classification, as it applies to the *Acer*, *Liquidambar*, and perhaps to other species. A branch of the tree and some old leaves and fruits were submitted to M. Fauvel, but the fruits had lost their seeds, and the leaves were too old and decayed to be considered as good specimens for identification. But at first sight he recognised the fruits as those of a *Liquidambar;* the leaves were all trifid, palmately nerved, some slightly serrated, some with a smooth edge. But they were too old to show any signs of gland in the serration. They differ from those given to the *Liquidambars* in general, and from the *L. Orientale* and *L. Chinensis* varieties. M. Fauvel thinks the wood may belong to the *L. Formosana*, but must defer any definite opinion until the leaves and flowers are out. It is somewhat curious that there should be any mystery at this time of the day about so common a substance as the wood of a Chinese tea-chest.

THE last number (16) of the *Excursions et Reconnaissances*, the official publication of the Colonial Government of Cochin China, contains as usual several papers of scientific interest on that region. The first is a report by two engineers, MM. Viénot and Schrœder, of a survey undertaken for railway purposes of the country from Haiphong to Hanoi. The first part of the line from Haiphong to Haidong is about 45 km. in length, and the writers of this report describe the physical features of the district, the courses of the rivers, the villages, towns, and cities, the various productions—in short, everything bearing on the question of the construction of a line through the place. This is followed by a translation of a Chinese work on the mines of Cochin China, from which it appears that useful and precious metals are to be found there, and were at one time worked with success, although owing to the defective native methods the work had to be given up. M. Aymonier also contributes some interesting notes on the customs and superstitious beliefs of the Cambodians.

ACCORDING to the *Japan Weekly Mail*, the meteorological system of Japan now comprises twenty-three observatories in the most important places throughout the country. Reports are sent from each district to the central observatory in Tokio three times a day, and are there thrown into suitable form for publication by the leading journals in the capital and the open ports. To a German, Dr. E. Knipping, belongs the credit of elaborating and perfecting the whole system. In China, the Shanghai Chamber of Commerce has also assisted Père Dechevrens in his meteorological work by making him an annual grant of about 300*l*.

A RECENT writer in the *North China Herald* discusses the part played by mercury in the alchemy and *materia medica* of the Chinese. Cinnabar was known to them in the seventh century before the Christian era, and its occurrence on the surface of the earth was said to indicate gold beneath. Their views on the transformation of metals into ores and ores into metals by heat and other means took the form of a chemical doctrine about a century before Christ, and there is now no reasonable doubt that the Arabian Geber and others (as stated by Dr. Gladstone in his inaugural address to the Chemical Society) derived their ideas on the transmutation of metals into gold and the belief in immunity from death by the use of the philosopher's stone from China. Among all the metals with which the alchemist worked, mercury was pre-eminent, and this is stated to be really the philosopher's stone, of which Geber, Kalid, and others spoke in the times of the early Caliphs. In China it was employed excessively as a medicine. On nights when dew was falling, a sufficient amount was collected to mix with the powder of cinnabar, and this was taken habitually till it led to serious disturbance of the bodily functions. In the ninth century an Emperor, and in the tenth a Prime Minister, died from overdoses of mercury. Chinese medical books say it takes two hundred years to produce cinnabar; in three hundred years it becomes lead; in two hundred years more it becomes silver, and then by obtaining a transforming substance called "vapour of harmony" it becomes gold. This doctrine of the transformation of mercury into other metals is 2000 years old in China. The Chinese hold that it not only prolongs life, but expels bad vapours, poison, and the gloom of an uneasy mind.

THE Peabody Institute of the City of Baltimore is an educational institution founded in his native city by the rich philanthropist, and worked for the advantage of a rather higher class of students than those of the ordinary free library. It combines under one government, as we have before urged the advantage of combining, the library, the lecture-room, music, and art, besides an annual expenditure in prizes for certain schools in Baltimore; and each department is managed by a sub-committee so small as to make every member of it probably feel himself greatly responsible for its success. The lecture committee provided six lectures each upon "The Sun and Stars," and "The Yosemite Valley," &c., and four lectures each upon "The Crusades," "The Minds of Animals," and "Shakespeare's Plays," all except the last assisted by illustrations. These formed a series of two lectures weekly during the four winter months, and season tickets were sold at a price not much exceeding threepence a lecture, the expense to the Institute being about 100*l*. The Conservatory of Music sets itself a high ideal, and claims considerable success. It employs five professors of music, who have had 160 pupils under them, but no pupil reached the level of earning their diploma. A series of fifty-one lectures, concerts, and rehearsals were given, to all of which annual subscribers are free at a small cost similar to that of the lectures, with a charge upon the Institute of about one-seventh of the entire amount spent in the cultivation of music. Upon a Gallery of Art open for eight months during the year, and helped by a loan of pictures, the Trustees were unable to spend any capital sum, and the expenses were limited to the care-takers. Over 1200 dollars were spent according to

Mr. Peabody's will in premiums and medals given to four schools in Baltimore. The library, however, is the object of largest expenditure, and aims at being a high-class one in every respect, 12,000 dollars, or one-quarter of the entire expenditure, having been laid out in the purchase of books. Important and uncommon works are added, supplying the demands of scholars for minute information. Such students are its most numerous users, and there were but few works of fiction among the 2700 volumes added during the past year. The library now reaches a total of 82,000 volumes. A catalogue of these is being compiled, the first volume of which, heartily recommended by many scholars and bibliographs, and already leading to greater use of the library periodicals, contains 868 pages and 61,184 references, yet only takes in A–C. We are told that it is offered under cost price at seven dollars to subscribers, but the Provost's remark which follows, that, besides being very expensive, "it is not desirable to sell many copies," shows how little the Institute aims at popularity. And in no department, truly, can this be boasted of! The lectures seem to have been the most successful. The Report observes that the annual members of the Conservatory of Music ought to rise to 400 or 500 instead of 87; and 70 visitors a day is not many, out of a population of nearly 400,000, to the Gallery of Art. Less than 60,000 issues have been made out of the great library, and the Provost thinks that the public will be surprised to hear that a total of 100,000 persons have visited the buildings for its various purposes during the year! These numbers show how, in America as well as in England, a small rise in requirements brings one into a much rarer, less crowded stratum of society. However, in all departments increased interest and "remarkable progress" are reported, which we trust may increase tenfold.

At a meeting of the Vaccination Officers' Association held on Saturday last, a cordial vote of thanks was given to the National Health Society for issuing their pamphlet entitled "Facts concerning Vaccination," and the Association expressed their appreciation of "the thoughtful kindness which prompted the Society to assist the vaccination officers of the metropolis in the discharge of their often difficult duties." We are informed that the pamphlet in question has now been distributed from house to house in most of the districts in the metropolis where small-pox is epidemic, and that the demand for it still continues. Something like 150,000 copies have already been issued since the present epidemic began.

As a supplement to our note of a meteor seen on the west coast of Norway on May 27 (p. 200), it will be interesting to read the following particulars supplied by Mr. Gjestland, residing at Tysnas, in the province of Bergenhus. This gentleman states that he too saw the fire-ball a little after eight o'clock, and subsequently heard a report as of distant rolling thunder. A couple of days after he happened to be on a farm, Midtvaage, in Onarheims parish, where a woman told him that she had seen the "ball" fall a few feet from the house. On learning this Mr. Gjestland, in connection with the parish engineer, began a search in the direction indicated, and discovered, in a spot where the turf covers the mountain ridge to a depth of about 20 cm., a hole where the turf and mould had been as it were blasted away from the rock, and in it a handful of pulverised stone, which, however, in every respect seemed to resemble the mica schist of the mountain. Two days after he learnt that a girl on the same farm had found a very peculiar stone near the same spot, which was thought to be the one searched for. Mr. Gjestland at once proceeded to the farm, and has succeeded in obtaining the valuable specimen. He states that in shape and size it is like the fourth part of a large Stilton cheese, cut vertically from the centre to the side. The height as well as the diameter is 20 cm. A fresh fracture on the surface shows that a bit has been broken off, probably by striking the rock, while the other side shows an uneven, undulating surface partly polished. The exterior is sooty and dark in colour, indicating that it had been exposed to great heat, whilst the interior is grayish brown and interspersed with bits of metal having the appearance of iron, some of which are 1 mm. in length. The block has a considerable specific weight, resembling that of iron-stone, is brittle, and may be cut with a knife. The weight is 19·5 kilos.

On July 3, at 9.32 p.m., a brilliant meteor was seen in Stockholm, crossing the sky from south-east to north-west, about 22° from the zenith. The colour was first red, then yellow and green, and became finally white as the meteor parted into halves about 45° above the horizon. It afterwards burst into fragments. When at its point of culmination, the meteor had the appearance of a kernel about a third of the moon's disk in size, with a trail of about the same width and ten times the diameter in length. The whole lasted about four seconds.

The French Northern Railway Company have begun experiments on motive power generated by electricity at the Chapelle Station. The Company have established an electric lift with two Siemens electro-magnetic machines, one for elevating the weight, and the other for moving the machinery alongside the railway.

During the night of July 19 an earthquake was felt at Agram. It lasted four seconds, and was accompanied by subterranean rumblings. No damage was done.

An unknown benefactor recently offered to give 100,000 marks to the University of Heidelberg, on condition that ladies should be permitted to study there. The University has declined the offer.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mrs. A. Edwards; a Gray Ichneumon (*Herpestes griseus*) from India, presented by Lieut. A. H. Oliver, R.N.; a Short-toed Eagle (*Circaetus gallicus*), South European, presented by Mr. W. R. Taylor; a Bronze-winged Pigeon (*Phaps chalcoptera*) from Australia, presented by Mr. J. Latham; five Natterjack Toads (*Bufo calamita*), British, presented by Mr. W. Stanley; three Striolated Buntings (*Emberiza striolata*) from Africa, deposited; a Four-horned Antelope (*Tetraceros quadricornis*) from India, a Maccarthy's Ichneumon (*Herpestes maccarthiæ*) from Ceylon, three Common Squirrels (*Sciurus vulgaris*), British, six Aldrovandi's Lizards (*Plestiodon auratus*) from North-West Africa, purchased; two Virginian Deer (*Cariacus virginianus*), an Argus Pheasant (*Argus giganteus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

Brorsen's Comet of Short Period.—We are now within about two months of the probable time of the next perihelion passage of this comet, and after the middle of August, when the moon draws away from the morning sky, it may be within reach. So far, however, no ephemeris for this return has been published. The perturbations since its last appearance in 1879 will not have been very material, and the mean motion in that year would fix the approaching perihelion passage to about September 14·5 G.M.T. If the longitudes in Dr. Schulze's orbit for 1879 are brought up to 1884·75, the following expressions for the comet's heliocentric co-ordinates result:—

$$x = r \,.\, [9{\cdot}94286] \,.\, \sin(v + 207^\circ\ 56'{\cdot}7)$$
$$y = r \,.\, [9{\cdot}98506] \,.\, \sin(v + 126\ \ 22{\cdot}0)$$
$$z = r \,.\, [9{\cdot}73705] \,.\, \sin(v + \ \ 60\ \ 33{\cdot}4)$$

Taking September 14·5 for the epoch of perihelion passage, the comet's approximate positions are:—

12h. G.M.T.	R.A. h. m.	Decl. ° ′	Distance from Earth	Distance from Sun
August 16 ...	7 7·7	+ 8 8 ...	1·282 ...	0·815
18 ...	7 20·0	8 46		
20 ...	7 32·5	9 25 ...	1·280 ...	0·766
22 ...	7 45·2	10 2		
24 ...	7 58·0	10 37 ...	1·284 ...	0·720
26 ...	8 11·0	11 10		
28 ...	8 24·2	11 40 ...	1·295 ...	0·679
30 ...	8 37·5	12 8		
September 1 ...	8 51·0	+12 33 ...	1·312 ...	0·644

If we suppose an acceleration of four days in the time of perihelion passage, the effect on the geocentric position is—

On August 16, in R.A. + 15·1. in declination + 2 1
On „ 28, „ + 16·7, „ + 1 41

The theoretical intensity of light expressed in the usual manner would be 0·92 on August 16, and 1·40 on September 1.

During the above period, with the places assigned, the comet would rise at Greenwich from 2h. 10m. to 2h. 20m. before the sun. In 1873, when the circumstances approached nearest to those of the return in the present year, the comet was detected at Marseilles on the morning of September 2, the distance from the earth being 1·02, and that from the sun 0·94, the intensity of light 1·08. At its last appearance in 1879 it was seen by Tempel at Arcetri, on January 14, when the intensity of light was only 0·13, an exceptional case, since at no previous appearance had it been observed under a less value than 0·33.

From the first discovery of the comet in 1846 by Brorsen, an astronomical amateur at Kiel, the period of revolution has gradually diminished from the effect of the planetary perturbations; subjoined are the times of perihelion passage in those years when the comet has been observed, and the sidereal periods corresponding to those times:—

		Days
1846 February	25·37 G.M.T.	2034·1
1857 March	29·25 „	2022·7
1868 April	17·41	2002·4
1873 October	10·48	1999·4
1879 March	30·54	1994·9

From its unfavourable position the comet was missed at its returns in 1851 and 1862. It is well known that the present orbit is due to the action of the planet Jupiter in 1842: at the perijove passage at 6 p.m. on May 27 in that year the comet's distance from Jupiter was 0·0547 of the earth's mean distance from the sun; consequent upon this near approach, the inclination of the orbit in which it previously moved was diminished nearly 15° according to the calculations of Dr. Harzer, who has very fully investigated the circumstances It is probable that there had been a great perturbation of the elements from the same cause in 1759-60, and that in 1937 (according to D'Arrest) this may again occur.

THE BINARY-STAR β DELPHINI.—Dr. Dubjago, of the Observatory at Pulkowa, has published a first orbit of this star, the duplicity of which was discovered by Mr. Burnham in 1873; more than 180° of the orbit have been described since that year. The period found is 26·07 years, the periastron passage at 1882·19. After that most rapid of all the known revolving double-stars δ Equulei, to which Mr. Burnham attributes a period of only 10·8 years, there is only one, 42 Comæ Berenicis, that has a shorter revolution attached to it, and β Delphini may be eventually proved to have the less period. In 1873 Mr. Burnham estimated the distance of the components 0″·7; they have since closed until the star has been beyond the powers of any but the largest telescopes. Dr. Dubjago's elements assign for 1884·6 position 219°·4, distance 0″·28.

RED SUNSETS[1]

THE equatorial diameter of the earth is 7901 miles and the circumference is 24,825, and as she revolves once on her axis in twenty-four hours, a place on the equator moves through 1034 miles in an hour: but at any depth beneath the surface the velocity is less in proportion to that depth; in like manner, if we look on the atmosphere as part and parcel of the earth, at a certain height the velocity is greater in proportion to that height.

The whole world has been greatly interested during the last seven or eight months with the beautiful phenomena of coloured suns and brilliant sunsets; and the liveliest interest has been exhibited as to their origin. Lockyer was the first, I believe, to point out the fact of the phenomenon of coloured suns appearing first in the east and then gradually shifting to the west. He traces them to Panama, and speaks of them as having been seen on a north-south line; but it strikes me that after leaving Panama the phenomenon passed still further westward, was seen on September 3, 4000 miles west of Panama, and at Honolulu on September 5, and struck India and Ceylon on the 8th, thus performing more than a complete circuit of the globe; moreover, I am of opinion that it may be traced still further westward, where it was seen in lat. 24° 6′ N., long. 140° 29′ W., by Capt. Penhallow of the barque *Hope*, on September 25, having then performed 2¾ revolutions of the globe.

All the information that I have collected, and from which I have compiled the following tables, has been obtained from NATURE. The time column has been deduced from the time and date of the phenomenon appearing at the different stations, reduced to Krakatoa time; in some instances great difficulty has been experienced, especially in reference to the time at Maranham in Brazil, and at Trinidad, and it has been concluded that at those stations the times are late, because it was seen at Panama before the time given at them, which we suppose to be an error. Likewise in the case of the Gold Coast, in one place the date given is August 30, and in another September 1, but from the general result it would appear to have reached that locality about midnight August 30-31.

The tables, I trust, are sufficiently clear; the first column of miles represents the mean diurnal velocity that the cloud travelled at between Krakatoa and the different localities *en route*; and in the subsequent columns are given the same from each station in rotation. Of course it will be understood that a small error of an hour or two in the time at the stations comparatively close to the eruption would make a large difference where we show the *diurnal* velocity; and as I have had only a week's notice to prepare this paper, I trust that any errors that may be hereafter found will be treated with that consideration.

TABLE I.—*Showing the Mean Diurnal Velocity in English Miles of the Phenomena of Coloured Suns and Brilliant Sunsets in the Northern Hemisphere*

Arithmetical mean for Northern Hemisphere 2105 miles per day.

The true mean of the first column, viz. that under the head of Java, is obtained by adding the distance between Krakatoa and each separate station together, and dividing the aggregate by the gross total number of days. The way by which the distance between any two stations is derived is by multiplying the difference in degrees of longitude by the value of a degree in English miles for the mean latitude of the two places. It must be remembered that between India and the last-named locality on the list the dust cloud is supposed to have performed over a revolution and a half of the earth.

I place great confidence in the result obtained from the observations deduced from India, because there there are scores of trained meteorological observers whose duty it is to immediately report any phenomena that may take place, and such as that concerning which I speak could not have escaped their immediate

[1] Paper read by Alexander Ringwood at an ordinary meeting of the Canterbury Philosophical Institute, New Zealand, on May 1, 1884.

notice; so we may conclude that the hour of its arrival there is very accurately determined, which gives a mean daily velocity of 2162 miles; and taking the velocity from its journey and a half round the world, from India to lat. 24° N., long. 140½° W., we find it to be 2192 miles per day, or 30 miles only in excess of the other computation. But if we take the whole journey from Krakatoa to that locality, about 2¾ revolutions round the globe, we find the mean to be 30 miles less than the first, or 2132 miles, and that will be accounted for through the diminished value of the degree in longitude at the mean latitude between Java and lat. 24° N., long. 140½° W.

The mean diurnal velocities obtained from the intermediate stations, between Java and India, agree very closely; when we consider that at those several places the phenomenon was wholly unexpected, and thus in most instances the dates and times given appear to be somewhat late, it is quite possible and natural that it escaped notice at least once; in India, however, we may conclude that they were on the alert, and consequently the mean velocity deduced from that place ought to bear great weight. There is another thing that ought not to be lost sight of, viz. that without this list of stations, more than encircling the globe, one might suppose that the *cloud* after leaving Krakatoa stretched away westward, and as I gather from Lockyer's paper by his *north-south* line, to have extended to the north and south, forming a letter V with the apex at the Straits of Sunda. Now Lockyer tracks it to Panama, to which place we see it to have had a diurnal velocity of 2059 miles, and from Panama to India I made it 2200 miles per day, which makes me believe that the cloud was performing a spiral path northward round the globe.

Before proceeding I will now turn to the observations in the Southern Hemisphere, in order to see whether the same has taken place there. This table has been prepared in like manner to the former, viz. the dates and times are reduced to that of Krakatoa, and the distances in English miles obtained from the difference in degrees of longitude reduced to the value of the mean latitude of the two places.

TABLE II.—*Showing the Mean Diurnal Velocity in English Miles of the Phenomena of Coloured Suns and Brilliant Sunsets in the Southern Hemisphere*

	Time from Java to	Java	Mauritius	Adelaide	Cape of Good Hope
	hours				
Mauritius	44	1680			
	days				
Adelaide	21¼	2041	1980		
Cape of Good Hope	24	2082	2047	2010	
Christchurch	29¼		1990	2120	2070
Arithmetical means		1984	2005	2065	2070
True mean		2100			

Arithmetical mean for Southern Hemisphere 2031 miles per day.

The marked similarity between these two tables is most striking, and, as in the first table, the greatest discrepancy is found between Krakatoa and Mauritius, where the data are reckoned in so many hours, in which case an hour or two makes a material difference in the diurnal velocity. At present I cannot find any station reporting the phenomenon between Mauritius and Adelaide, but we may conclude that after it passed Mauritius it crossed Africa, the South Atlantic, and South America, whence we may expect to hear of it, as there are many competent observers in that part of the world; it then traversed the great South Pacific Ocean and North Australia, and after performing another such journey round the world, but in a higher latitude, was seen at Adelaide in South Australia about September 17. [illegible] Cape Good Hope on September 20. It again crossed the South Atlantic and South America about the latitude of Buenos Ayres, and a third time traversed the South Pacific, striking the coast of New Zealand on September 25, the date of my first seeing it; on which occasion the western sky at sunset presented all the colours seen in the pearl-shell. Since then the western and eastern skies have presented those beautiful crimson tints that have delighted the world, and on many occasions I have seen it almost in the zenith two hours after sunset. During some evenings it has quite illuminated the western face of buildings with a bright glare as from a fire, whilst on others it has been very faint and sometimes not discernible: giving to my mind the idea of its not being a continuous band but a series of dust clouds with clear spaces between.

From an investigation of the two tables it will be seen that the mean diurnal velocity in the Northern Hemisphere was, during the first revolution, about 2162 miles, and during the second it increased to 2192, or 30 miles per diem extra. And the same increased velocity is observed in the Southern Hemisphere, where we find the approximate velocity during the first two revolutions, viz. on its reaching Adelaide, to be 2041, whereas during the next revolution from Adelaide round to New Zealand it was 2120 miles, or an increase of 80 miles per day. It will be further noticed that in the Northern Hemisphere the time occupied in its first revolution was about eleven days, and the same rate is observed during the next revolution and three-quarters, or, in other words, within the tropics it encircled the world in eleven days. It is the same within the southern tropics, where it took 21¼ days to reach Adelaide in its second revolution, but it performed the next revolution in about 9½ days, reaching New Zealand in 29¼ days after the eruption. Thus it performed 2¾ revolutions in the Northern Hemisphere in 29⅝ days, and in the Southern Hemisphere it performed 2¾ revolutions in 29¼ days, showing that the initial velocity at starting has only very slightly fallen off in even latitude 45° S. So in the following discussion I will adopt a mean diurnal velocity for the dust cloud of 2083 miles, or 87 miles per hour to the westward.

As I showed at the beginning that, if the atmosphere be considered as part and parcel of the earth, a particle of it at a certain height will cover a greater distance in a certain time than that part of the earth immediately beneath would, so if we know the rate per hour that a certain thing *apparently* moves to the westward, or seems to lag behind the diurnal revolution, we can ascertain the height. We know that it lags behind at the rate of 2083 miles per day, which, added to the circumference of the world, gives a circle of 26,908 miles, and this divided by 3·1416 gives a diameter of 8565 miles, or 664 miles greater than that of the earth, or a height of 332 miles above the surface. Or, putting it this way, we may assume that at the latitude of Krakatoa the earth has an hourly velocity of 1034 miles, and that any matter ejected thence into the upper regions of the atmosphere, would retain the same rotary velocity as it had before, viz. 1034 per hour to the eastward; but we have material under our observation which cannot keep its zenithal position at starting, by 87 miles per hour, showing it to be at an elevation of 332 miles.

Now the spectroscope tells us that the red colour is produced through dust of almost ultra microscopic fineness, and in some specimens of this dust that have already fallen the microscope shows the existence of *salt* crystals, which fact in itself almost proves it to be of volcanic origin, and not meteoric or cosmic dust. Now Prof. Helmholtz states that "the reflecting medium, whatever it was, over Berlin on the last three nights of November, was about 40 miles above the earth;" and if we work on this data we have a circle whose diameter is 80 miles greater than that of the earth, or a circle of 7981 miles, which, multiplied by 3·1416 gives a circumference of 25,073, or 248 miles more than that of the earth, which, divided by 24, shows an excess of about 10¼ miles per hour above the surface velocity of rotation. But we want to account for an excess of 87 miles per hour; so if we accept Prof. Helmholtz's statement we must only suppose that at the altitude of 40 miles there is an easterly current, or one moving to the westward, of 77 miles per hour; for, assuming as we do from the foregoing tables and calculations that the earth rolls from under the cloud at the rate of 87 miles per hour, unless we admit of an easterly current we cannot stop short of that enormous height of 332 miles unless we suppose that the power of gravitation has only a feeble hold on those most minute dust particles at the altitude of 40 miles, where the atmosphere has not the many thousandth part of the density it has on the surface of the globe.

Mr. W. H. Preece writes stating his opinion that the mass of matter ejected retained the same electric sign as that of the earth, and as long as that was the case the repulsion force would be sufficient to keep the matter afloat; and in reference to that theory Mr. Crookes writes to state that with a rarefaction of one-millionth of the atmosphere, two pieces of electrified gold leaf repelled each other at a considerable angle for thirteen mon[illegible]and goes on to state that that rarefaction is attained at

an altitude of 62 miles, and that the air there is a perfect non-conductor of statical electricity, without interfering with the mutual repulsion of similarly electrified particles; and when we bear in mind that the particles of minute dust are many thousands of times smaller and lighter than the gold leaves operated upon, there is every reason to believe that electrified dust, once projected 50 or 60 miles high, might remain there many years.

Before proceeding further I must draw your attention to the fact that at the time of the great eruption, and during September, the mean temperature at Batavia, and throughout Java generally, is at its maximum; consequently we may conclude that the equatorial belt of calms and uprushing air that encircle the globe was lying over that district at the time. This uprush is caused through the heated atmosphere rising, and the two trade winds, the north-east and south-east, feed it. When this heated air has attained its proper altitude, it flows off to the north and south, but the rotation of the earth causes it to flow towards the north-east in the Northern Hemisphere, and to the south-east in the Southern Hemisphere, and these winds are called by some the return trades, and by others the south-west and north-west upper currents respectively, and are of great altitude, probably ranging up to 50,000 feet.

Well, the most bulky masses cast upwards by the eruption of Krakatoa would immediately fall, and the less bulky would fall later according to their size, but the great portion of the dust and ash would be caught, on its downward course, in those upper currents just alluded to, and be carried by them to the north-east and south-east. Such we find to be the fact, for the ship *Meda*, when to the westward of Cape North-West, Australia, or about 1050 miles south-east of Krakatoa, experienced a fall of dust like fuller's earth, which covered the vessel, on the night of August 30-31, and Capt. Tierney, of the brig *Hazard*, on September 1, near New Ireland, a distance of 3850 miles due east of Krakatoa, saw the coloured suns, which was no doubt due to the presence of du-t in the atmosphere, drifted eastward with the upper current.

Now, turning to the north-east quarter, or the direction in which the south-west upper current of the Northern Hemisphere proceeds, we find that in Japan during August 29, 30, and 31, the sun was of a copper colour, and had no brightness in it; at Yokohama, Mr. Hamilton states that on the 29th and 30th the sun was of a blood-red colour, and appeared to be obscured. This is at a distance of about 3000 miles from Krakatoa, which gives a velocity of the upper current, or return trade wind, of about 62 miles per hour; this is not excessive, as I have often measured the velocity of the north-west upper current at Adelaide as over 80 miles per hour.

You may remember that I did not continue the tracking of the dust cloud, from that position assigned to it by Capt. Penhallow, in lat. 24° N., long. 140½° W., on September 25, because the European and American reports are so peculiar. It was apparently seen in England *before* the rest of Europe, viz. on November 4 and 9, in California on the 20th, San Francisco on the 23rd, Italy on the 25th, New York on the 27th, and at Berlin on the 28th; so you see that the geographical arrangement is rather mixed in reference to the order of dates. This may be accounted for by the fact that there was a very severe volcanic eruption in the Alaska Group and Peninsula in October, I think; it was very intense, and quite capable of ejecting a dust cloud that would envelope the Polar and temperate regions of the Northern Hemisphere; of course it was not nearly so terrific as that of Krakatoa. So you will see that we must be careful before we assert that the brilliant sunsets of Europe are of Krakatoan origin.

The phenomena of coloured suns and brilliant sunsets, I may tell you, have been seen before, both in Europe and America, in connection with Vesuvian and Iceland outbursts; Mr. Somerville, the famous geographer, gives an instance of it which had been seen in Norway, and traced its origin to a severe eruption in Iceland. And H. C. Russell, B.A., F.R.A.S., F.R.Met.S., Government Astronomer, Sydney, in his book on the climate of New South Wales, pages 187, 188, gives some most interesting instances of historical accounts of darkened and coloured suns. I will quote them in their chronological order:—

"'At certain times the sun appears to be not of his wonted brightness, as it happened to be for a whole year when Cæsar was murdered, when it was so darkened that it could not ripen the fruits of the earth.' — Virgil, *Georg.*, lib. i., &c.

"In 1090 there was a darkening of the sun for three hours.

"In 1106, beginning of February, there was obscuration of the sun.

"In 1208 there was a darkening of the sun for six hours.

"In 1547, August 24 to 28, the sun was reddish, and so dark that several stars were visible at noonday.

"In 1706, May 12, about ten o'clock in the morning, it became so dark that bats commenced flying, and persons were obliged to light candles.

"In 1777, June 17, about noon, Messier states that he perceived an immense number of black globules pass over the sun's disk.

"In 1783 there was a *dry fog*, and many attributed it to volcanic action; and it is well known that in February that year fearful earthquakes in Calabria took place, followed by a long list of volcanic eruptions in other parts of the world.

"In 1831 was an extraordinary *dry fog*, which excited public attention throughout the world. It appeared on the

Coast of Africa	August	3
At Odessa	,,	9
In South France	,,	10
Paris	,,	10
New York	,,	15
Canton, China	,,	end of.

This fog was so thick that it was possible to observe the sun all day with the naked eye, and without a dark glass, and in some places the sun could not be seen till it was 15° or 20° high. At Algiers, United States, and Canton the sun's disk appeared of an azure blue or of a greenish colour. Where the fog was dense, the smallest print could be read even at midnight.

"In 1873, of the *dry fog* which came on suddenly in June, it is recorded that it extended from the northern coasts of Africa, over France to Sweden, and over great part of North America, and lasted more than a month. Travellers found it on the summit of the Alps. Abundant rains in June and July and most violent winds did not dissipate it; and in some places it was so dense that the sun could not be seen until it had attained an altitude of 12°, and throughout the daytime it was red, and so dull that it might be looked at with the naked eye. The fog diffused a disagreeable odour, and the humidity ranged from 57 to 68, while in ordinary fog it is 100. It had a phosphorescent appearance, and the light at midnight was compared to that of full moon."

Here was exhibited a diagram, drawn correctly to a scale of fifty miles to one inch, showing the arc (15°) of a circle whose radius was 6 feet 7 inches, or a diameter of 13 feet 2 inches. The Himalayas were shown in their correct proportion, so was the smoke from Cotopaxi, estimated by Whymper while on Chimborazo at 40,000 feet; he saw at 5.45 a.m. of July 30, 1880, a dense column of smoke shot up straight into the atmosphere with prodigious velocity, which in less than one minute had risen 20,000 feet above the crater, giving the total height of 40,000 feet above sea-level. The dust, he goes on to state, fell on Chimborazo after six hours, and he estimated that each particle did not weigh 1/25000 part of a grain, and the finest were still lighter.

Some people (and very rightly too) express wonder and unbelief at the possibility of *dust* being capable of having been shot up to such a height as that ascribed to it, as to cause the red sunsets,—but here I have quoted the fact of such, as seen by a man of known repute; the dust and ashes *were shot up* to that great height, and not only that, but as the dust cloud came between Mr. Whymper and the sun, he saw the phenomenon of the coloured suns. The same may be seen during any very heavy dust storm anywhere, when the cloud is between the observer and the sun.

In this description given by Whymper, we have a good illustration of the tremendous force Nature uses in these convulsions; a force that could throw the finest dust to a *height* of 20,000 feet is almost inconceivable to the human mind, and in that phenomenon we have, I may say, only an everyday occurrence when compared with that giant eruption of Krakatoa. Let us draw a comparison. At the destruction of Pompeii, situated at the *foot* of Vesuvius, the city was enveloped with darkness from the density of the dust and ash cloud that enshrouded it, and that ultimately buried it; but now contemplate the tremendous power that ejected from a mountain a sufficiency of dust and ash

envelop a city in total darkness for thirty-six hours, *eighty miles distant*. On that diagram I have sketched an imaginary picture of the eruption, and eighty miles distant is represented by a little over an inch and a half, where you see the letter B, showing to your mind the relative distance of Batavia from Krakatoa. You can form in your imagination some idea of the great height that the dust cloud ascended: to my mind twice forty would not be too great. Then again we have the ship *Charles Bal*, when *thirty miles distant*, was enveloped at noon-day in pitch darkness through the mud-fall. Furthermore, as Lockyer says, the sound, the least part of the affair, was heard over an area of 4000 miles in diameter, viz. in Ceylon to the north-west, at Saigon to the north, and throughout North Australia to the south-east. In the last quarter the reports were at intervals of fifteen minutes, and sounded like ship-guns, but as the hearers were from 150 to 200 miles from the coast, such cause could not be assigned. All that can be said is that it is beyond the human mind to conceive of such gigantic forces, and therefore absurd to throw doubt on the result; by which I mean that if the laws of refraction show that the substance, whatever it may be, that causes the red glow, is at an altitude of forty or sixty miles, it is ridiculous to doubt that result, when we cannot conceive the magnitude of the power that operated.

It was not only one eruption that took place, but several, during the 26th, the following night, and up to 11.15 a.m. of the 27th, about which time the grand finale is supposed to have taken place. These eruptions followed each other in rapid succession, and are thought to have been caused by the rapid conversion into steam of vast quantities of water that found admittance into the bowels of the earth. Later on the influx of water was too much, and the result was that a tremendous power was generated, so much so as to cause the north part of the island to be blown away, and fall eight miles to the north, forming what is now called Steers Island. This was followed by a still greater eruption, when it is thought that the north-east portion was blown clean away, passing over Long Island, and fell at a distance of seven miles, forming what is now known as Calmeyer Island. These suppositions are almost proved to be facts, from the Marine Survey of the Straits just concluded, from which it will be seen that the bottom surrounding these new islands has not risen, which would most naturally have been the case had they been caused by upheaval, but if anything the bottom shows a slightly increased depth in the direction of the great pit that now occupies the position that the peak of Krakatoa did the day before. These incidents are cited to show you the awful nature and magnitude of the forces brought into play, as you can the more readily satisfy your minds as to the great height the dust and ash were thrown to.

As I said before, this dust cloud may probably be denser in some places than others, owing that fact to the relative period of time that elapsed between each eruption; where it is dense we may assume that they followed each other rapidly, and where it is less dense the interval of time was greater. For you must remember that it was shown to you that the cloud apparently moves to the westward, or that the earth moves from beneath the cloud, at the rate of 87 miles per hour, so that during each hour of the eruption there was a long streak of smoke and dust being formed. These densest parts were no doubt the cause of the coloured suns, and as some observers state, "the sun appeared to shine with diminished strength," others "that it was rayless and giving no heat," so we may look upon that dust cloud as playing the part of a great screen, shutting off some of the heat of the sun from us. In these southern latitudes we have experienced those brilliant sunsets for over seven months, and I have no hesitation in expressing my opinion that the remarkably cool and wet summer just passed in New Zealand was due to that dust cloud shutting off the sun's heat in a great degree. And I see from the Adelaide report that the mean temperature there during January was over 4½ degrees cooler than the average of the previous twenty-five years, and on only one occasion during that period was it so low, viz. in 1869. At Melbourne also the weather was more like winter than summer, whereas in North and Central Australia, or I may say down to lat. 30° on that continent, the weather was fine, clear, and hot, without rain, giving me the idea that the sun had less power than usual; consequently the north-west monsoon was very feeble, not penetrating far inland, the result being that the interior of Australia has undergone one of the most disastrous droughts on record. But now that, as we may suppose, the equatorial regions of the atmosphere have parted with the greater part of their dust, if not all, the sun has regained his usual power, and the north-west monsoon its usual strength, penetrating the heart of Australia with refreshing rains and thunderstorms. So we have here an instance of a most terrific phenomenon that not only brought death and destruction to thousands at the time, but that indirectly caused the death of thousands and thousands of cattle and sheep through drought, and it would be most interesting and instructive to learn whether or not such consequences were experienced in other parts of the Southern Hemisphere at least.

It would be beyond the province of this paper, and in fact too late to-night, to enter on a history of the tidal and atmospheric waves that resulted from this eruption, but I will state two facts to finally clinch your mind of its magnitude. When the earth opened her mouth and swallowed that vast quantity of water, the down-rush that accompanied the closing-in of the surrounding crust was so much as to produce a tidal wave that passed and repassed twice, I believe, round the globe. The other fact is, that the tremendous explosion that accompanied the final eruption produced such a vacuum as to cause atmospheric waves to start, and which traversed and retraversed the earth to the antipodes of Krakatoa no less than four times.

Some astronomers have thought that the whole phenomenon may be accounted for by supposing the earth to be passing through a dense meteoric track. To my mind, however, the greatest difficulties brought to bear against the volcanic theory are child's play when compared with the possibility of about 10,000,000,000 to one of a meteoric track so formed as to have its path, either at aphelion or perihelion, so remarkably coincident with that of the earth as to keep company with her for seven or eight months. Besides, were it either meteoric or cosmic dust, it would be seen all over the earth at the same time, and would be visible all night.

No; the only extra-terrestrial argument that would bear any investigation is that of its belonging to the phenomenon of the zodiacal light, which argument, I believe, was adopted at first by my friend Charles Todd of Adelaide; but, as time goes on and more information is gathered, the volcanic theory, I believe, will be finally adopted.

THE THEORY OF THE WINTER RAINS OF NORTHERN INDIA [1]

AT first sight, the occurrence of rain in Northern India at the season when the north-east or winter monsoon is at its height seems to present a meteorological paradox. The well-known theory of the winter monsoon is that at that season the barometer stands highest in North-Western India where the air is cold and dry, and lowest in the neighbourhood of the equator where it is warm and moist; and therefore, in accordance with elementary mechanical laws, the wind blows from the former to the latter. But the precipitation of rain requires that the air should have an ascending movement, and this can take place only over a region of low barometer, towards which, therefore, the winds are pouring in. Hitherto no one has attempted the reconciliation of these apparently discrepant conditions.

Since the establishment of a Meteorological Department under the Government of India has rendered it possible to study the weather of India as a whole from day to day, it has been my practice to investigate every case of cold weather rainfall in Northern India, amounting generally to three or four in each year, and although many important points still remain for elucidation, it is now at least possible to clear up many of the difficulties of the problem, and to reconcile the apparent inconsistencies.

The charts which accompany the paper show the distribution of atmospheric pressure and the prevalent winds in the four months of the cold weather. They exhibit many features in common. The region of highest barometer is in the Punjab and the Indus Valley, and from this an axis or ridge of high pressure extends across Rajputana and Central India, having a trough of slightly lower pressure in the Gangetic plain and the Northern Punjab on the one hand, and a much lower pressure in the peninsula on the other. The winter monsoon blows around this region of high pressure in an anticyclonic curve, *i.e.* in the direction of the watch-hands, but in the Punjab and the Gangetic plain there is but little movement of the air, the average rate

[1] Abstract of a paper read before the Asiatic Society of Bengal on March 5, 1884, by H. F. Blanford, F.R.S., President of the Society.

being less than two miles an hour, and calms constitute about one-third of the observations. Also it is shown, by the barometric registers of the Himalayan hill-stations, that that distribution of pressure which, on the plains, causes the north-east monsoon, does not exist and is even slightly reversed at an elevation of 7000 feet.

Hence, in Northern India, the state of things which produces the winter monsoon is restricted to a small height, and is then only an average and not a permanent condition; and that which chiefly characterises the atmosphere is its stillness, a condition in which any local action, small and feeble as it may be at first, may eventually set up a disturbance such as to revolutionise the existing conditions.

The cold weather rainfall is always the result of a local fall of the barometer, the formation of a barometric depression, which generally appears first in the Punjab or Western Rajputana, and then moves eastwards. Towards and around this depression the winds blow cyclonically (*i.e.* against the direction of the clock-hands), and the winds from the south, coming up charged with vapour which they have collected from the warmer land surface of the peninsula and sometimes from the sea, discharge this as rain chiefly to the east and north of the barometric minimum, where they form an ascending current.

Thus in the cold weather, rain generally begins in the Punjab and later on extends to the North-Western Provinces, Behar, and sometimes to Bengal. As the disturbance travels eastwards, it is followed up by a wave of high barometric pressure, and cool north-west winds, which usually last for a few days after the rain has cleared off.

The crucial point of the problem of the cold weather rains is, then, how to account for the formation of these occasional barometric depressions in a region where the barometer is generally high at this season. It has been suggested by one writer that they travel to us from the west across Afghanistan. This, however, can be only a guess in the dark, for, at the time it was made, there were no observatories to the west of India nearer than Bushire, at the top of the Persian Gulf. There is one now at Quetta, and I have examined the registers of this observatory to see if they give any support to the idea, and find that, with the exception of two doubtful instances, they do not. I conclude therefore that in most cases, if not in all, these disturbances originate in India, and their cause is to be sought for in the meteorological conditions of Northern India itself. In some instances they make their first appearance in Rajputana or Central India, and there can then be no question whatever of their purely local origin.

Now the region over which the winter rains are more or less regularly recurrent coincides with that in which the relative humidity of the air at this season, instead of diminishing towards the interior of the country, increases with the increasing distance from the coast. In any month between March and December, as we proceed from the coast of Bengal towards the Upper Provinces, the air becomes drier and drier, not only as containing an absolutely smaller quantity of water vapour, but also, in most months, in virtue of its increased capacity for taking up vapour, owing to its higher temperature. But from December to March the dryness increases inland only as far as Behar. Beyond this, although the quantity of vapour in the air remains very nearly the same or even undergoes a slight diminution, in virtue of the increasing cold there is an approach to that temperature at which this small quantity of vapour would begin to condense, forming cloud or fog; and it is in the Punjab that, in this sense, the air is most damp. The result is that which our registers show to be the case, viz. that from December to March it is also the most cloudy province. This seems to depend very much on the stillness of the air. The vapour that is always being given off from the earth's surface diffuses gradually upwards in the still atmosphere, and soon reaches such an elevation that it begins to condense as cloud. When once a moderately thick bank of cloud is thus formed, the equilibrium of the atmosphere is speedily disturbed. It is well known as a fact from Glaisher's balloon observations, and is also a consequence of the dynamic theory of heat, that the vertical decrease of temperature in a cloud-laden atmosphere is much slower (about one-third) than that in a clear atmosphere. This initial disturbance will suffice then to cause an indraught of air from around, an ascending current is set up, the barometer falls; warm, vapour-laden winds pour in from the south, and we have all the conditions of the winter rains.

If this view be just, the stillness of the atmosphere combined with the presence of a moderate evaporation must be accepted as the condition which primarily determines the formation of barometric minima and the winter rains of Northern India. And this stillness is obviously due to the existence of the lofty mountain ranges which surround Northern India, leaving free access to the plains open only to the south.

Were the Himalayan chain absent and replaced by an unbroken plain stretching up to the Gobi Desert, it is probable that the winter rains of Northern India would cease; any local evaporation in the Punjab and Gangetic valley would be swept away by strong, dry, north-east winds blowing from the seat of high pressure, which, in the winter months, lies in Central Asia, and instead of the mild weather and gentle breezes which now prevail at that season on the Arabian Sea, it would be the theatre of a boisterous and even stormy monsoon, such as is its local equivalent of the China Seas.

SCIENTIFIC SERIALS

Bulletin de l'Académie des Sciences de St. Pétersbourg, vol. xxix. No. 2.—On a new comet, by O. Struve. Its elements, calculated by Herr Seyboth, are:—T = 1884, January 23·225 average time of Pulkowa; $\pi = 92° 19' 39''$; $\Omega = 253° 22' 52''$; $i = 74° 21' 56''$; $\omega = 198° 56' 47''$; q = 9·87922. Dr. Struve considers it as identical with the comet of 1812, calculated by Encke, and adds a note, by Herm. Struve, about the sudden increase of its light on September 19 to 22.—A report on M. Backlund's memoir on the motion of the comet of Encke from 1871 to 1881, by O. Struve.—On petrified wood from Ryazan, by Prof. Mercklin; it is like *Cupressinoxylon erraticum*.—Observations on some propositions relative to the numerical function $E(x)$, by V. Bouniakovsky (third paper).—Remarks on Ginakîrti's "Kampakakathanâkaka," translated by A. Weber, by Otto Böhtlingk.—On the contact of inverse figures with the polar reciprocals of the directing figures, by J. S. and M. N. Vanecek.—Note on wollastonite, by N. Kokscharow.—Telephonic phenomena in the heart produced by the irritation of *nervus vagus*, by N. Wedenski.—On the use of the telephone for the measurement of temperature, by R. Lenz.—On terrestrial currents compared with magnetic variations, by H. Wild.—On the variability of the light of Y Cygni, by Ed. Lindemann. The observations were made in 1881 to 1883, and the magnitude varied from 6·8 to 10·4, showing an annual periodicity. The star changed its colour, as also its shape, becoming sometimes more nebulous, and the changes could scarcely be explained by mere conditions of observations.—Determination of the parallax of α Tauri, by Otto Struve. Its value, deduced from observations made in 1850 to 1857, is $0''·516$, with a probable error of $0''·057$.—On some arithmetical consequences of the formulæ for the theory of elliptical functions, by Ch. Hermite.—Note on the discovery of kalait in Russia, by N. Kokscharow.—Studies on milk (second and third papers), by Heinrich Struve; being a series of analyses of cows' and human milk, which bring the author to the conclusion that there are two kinds of caseine, the α-caseine and the β-caseine.—On the atmospheric waves produced by the Krakatoa eruption, by M. Rykatcheff.

Verhandlungen des Naturhistorischen Vereins der preussischen Rheinlande und Westfalens, fortieth year, 1883.—Contributions to the knowledge of the igneous rocks in the Carboniferous hills and New Red Conglomerates between the Saar and the Rhine, by H. Laspeyres.—On the trachyte of Hohenburg near Bonn, by the same author.—A study of the Devonian formations between the Roer and Vicht Rivers, by E. Holzappel.—Remarks on the loess of the Lahn Valley, by F. F. von Dücker.—Tertiary shingles of marine origin on the slate hills of Nassau and Ems, by the same author.—An account of some living American reptiles, spiders, and insects found at Uerdingen amongst the dye-woods imported for the Crefeld silk dyeworks, by F. Stollwerck.—Report on the prehistoric remains of the Sieg Valley, by Dr. M. Schenck.—On the development of the mining and smelting industries in the Sieg district, by H. Gerlach.—Remarks on some monstrosities and aberrations in the colour of the mammals of Westphalia, by Dr. H. Landois.—On the greenstone of the Upper Ruhr Valley and its association with the slates of the Lenne district, by A. Schenck, jun.—A description of some archæological remains from the Vlotho district, Weser Valley, by H. D'Oench.—A contribution to the study of the flora of the Rhenish Province, by M. Melsheimer.—A survey of the geological relations in the French Ardennes, by Prof. von

Lasaulx.—On the granites of the Watawa district, Bohemia, by Dr. J. Lehmann.—On the progress of electrical appliances, by H. Coerper.—Memoir on Anoplophora (*Uniona pohlig*), by Prof. von Koenen.—Obituary notice of Dr. Hermann Müller of Lippstadt, by Ernst Krause.—On the crystals of oxalate of lime present in the foliage and stem of *Iris florentina* (four illustrations), by Prof. von Lasaulx.—Remarks on a human skull and other human remains recently discovered in the loess of the Mosel near Metternich, by Prof. Schaffhausen.—Report of a geological excursion to the island of Corsica, by Prof. von Rath.—On the bacillus of tuberculosis and its presence in the human tissues, by Dr. H. Menche.—Remarks on some small crystals of leucite of unusual formation, by Prof. von Rath.—On ten small mammoth teeth from the Schipka Cave, Moravia (one illustration), by Prof. Schaffhausen.—On the action of bromide of aluminium on the dibromide of acetyl and on benzine, by Dr. Anschütz.—On a new synthesis of anthracene, by the same author.—Note on pyrites from the Gommern and Ploetzky sandstone, near Magdeburg, by Prof. von Lasaulx.—On the treatment of bites by venomous snakes, by Prof. Binz.—On a manganese and copper alloy, by H. Heusler.—Report of a scientific excursion in the island of Sardinia, by Prof. von Rath.—On the Tertiary formations of the Bonn district, by Dr. Pohlig.—On the naphtha and petroleum regions of Caucasia, by Dr. O. Schneider.—On the fossiliferous diluvium of the North German lowlands, by Dr. A. Remelé.—Microscopic examination of a series of Norwegian rocks from the Tromsoe district and the Lofoten Islands, by A. Philippson.—Effects of heat on the optical bearing of crystals, by W. Klein.—On the properties of racemic acid and of the inactive pyrotartaric acid of calcium, by Dr. Anschütz.—Geological and palæontological researches in the Bonn district, by Dr. Pohlig.—Microscopic examination of some specimens of volcanic matter from Krakatoa, by Prof. von Lasaulx.—Remarks on a new variety of glaukoppan from the island of Groix, on the west coast of Brittany, by the same author.

Rendiconti del R. Istituto Lombardo, May 29 and June 5.—Etruscan notes, by Prof. Elia Lattes.—Remarks on the laws affecting contract labour, by U. Gobbi.—On the colouring substances of putrefaction, and on some methods of discharging colours, by Dr. Paolo Pellacani.—On the supposed disposition to cretinism in patients operated on for affections of the parotid glands, by Dr. G. Fiorani.—A new determination of the latitude of the Brera Observatory, Milan, effected in the months of February and March of the present year, by L. Struve.—On a problem connected with the theory of stationary electric currents, by Prof. E. Beltrami.—On the nature of the colouring substance found in the urn of St. Ambrose, dating from the ninth century, by Prof. G. Carnellutti.—On the relation between the elasticity of some metallic wires and their electric conductibility, by Dr. G. Poloni.

SOCIETIES AND ACADEMIES

London

Geological Society, June 25.—Prof. T. G. Bonney, D.Sc., F.R.S., President, in the chair.—James Campbell Christie was elected a Fellow, and Baron C. von Ettingshausen, of Graz, a Foreign Correspondent of the Society.—The following communications were read:—Additional notes on the Jurassic rocks which underlie London, by Prof. John W. Judd, F.R.S. Since the reading of the former paper on the subject (February 6, 1884) the well-boring at Richmond has been carried to a depth of more than 1360 feet. The point reached is, reckoning from Ordnance-datum line, 220 feet lower than that attained by any other boring in the London basin. A temporary cessation of the work has permitted Mr. Collett Homersham to make a more exact determination of the underground temperature at Richmond. At a depth of 1337 feet from the surface this was found to be 75½° F., corresponding to a rise of temperature of 1° F. for every 52·43 feet of descent. The boring is still being carried on in the same red sandstones and "marls," exhibiting much false-bedding, which were described in the previous communication. The Rev. H. H. Winwood, of Bath, has had the good fortune to find the original fossils obtained by the late Mr. C. Moore from the oolitic limestone in the boring at Meux's Brewery in 1878. A careful study of these proves that, though less numerous and in a far less perfect state of preservation than the fossils from the Richmond well, they in many cases belong to the same species, and demonstrate the Great Oolite age of the strata in which they occur.—On some fossil Calcisponges from the well-boring at Richmond, Surrey, by Dr. G. J. Hinde, F.G.S.—On the Foraminifera and Ostracoda from the deep boring at Richmond, by Prof. T. Rupert Jones, F.R.S.—Polyzoa (Bryozoa) found in the boring at Richmond, Surrey, referred to by Prof. J. W. Judd, F.R.S., by G. R. Vine, communicated by Prof. Judd, F.R.S.—On a new species of *Conoceras* from the Llanvirn beds, Abereiddy, Pembrokeshire, by T. Roberts, B.A. Only five species of *Conoceras* have as yet been described; the author compared the Llanvirn species with these, and also with a fossil from the Devonian of Nassau, which Kayser referred to *Gomphoceras*, but which possesses several characters in common with *Conoceras*. The horizon from which this new species was obtained is that of the Llanvirn beds, some typical Llanvirn fossils having been found with it. The author named the species *Conoceras llanvirnensis*.—Fossil Cyclostomatous Bryozoa from Australia, by A. W. Waters, F.G.S. In the present paper the Cyclostomata from Curdies Creek, Mount Gambier, Bairnsdale, Muddy Creek, &c., Aldinga and River Murray Cliffs were described, bringing the total number of fossil Bryozoa from Australia, dealt with in this series of papers, up to 195, of which 85 are known living. Of the 32 Cyclostomata now dealt with, 12 at least are known living, and one cannot be distinguished from a Palæozoic form; 9 are apparently identical with European Cretaceous fossils. Although so many remind us of European Chalk and Miocene species, great stress was laid upon the imperfect data available for such comparisons, the Cyclostomata furnishing but few characters which are available for classification, which, so far, has, almost entirely been based upon the mode of growth, which, in the Chilostomata, has been shown to be of secondary value. In consequence of the few available characters, the Cyclostomata do not seem likely to be ever as useful palæontologically as the Chilostomata, and as they are less highly differentiated, it is not surprising to find that they are more persistent through various periods. In order to see how far other characters might be available, the author has examined Cyclostomata, both recent and fossil, from many localities and strata, and pointed out that the size of the zoœcia should always be noticed, as also the position of the closure of this tube. The arrangement of the interzoœcial pores may frequently give great assistance, and these are considered the equivalents of the rosette-plates; but the most useful character of all is no doubt the oвicell, which varies specifically in position and structure; but this unfortunately occurs on but few specimens, and has rarely been described fossil, although greater attention to this will no doubt lead to its being frequently found and noticed.—Observations on certain Tertiary formations at the south base of the Alps, in North Italy, by Lieut.-Col. H. H. Godwin-Austen, F.R.S.—On the geological position of the Weka-Pass stone, by Capt. F. W. Hutton, F.G.S. The beds described in this paper are of older Tertiary and newer Secondary age, and occur in the northern part of Ashley county, in the province of Canterbury, between the Hurinui and Waipara Rivers. All of the beds are met with at Weka Pass, on the railway and road between Christchurch and Nelson, and the following is the section in descending order:—(1) Mount-Brown beds; pale yellowish sandstone with bands of shells and coral limestone, considered by all New Zealand geologists upper Eocene or Oligocene; (2) gray sandy marl; (3) Weka-Pass stone, yellowish with arenaceous limestone, usually with small green grains; (4) Amori limestone, white, flaggy, and argillaceous; (5) green sandstone with remains of marine Saurians. The last rests conformably on beds of coal and shale, with leaves of dicotyledonous Angiosperms, forming the base of the Waipara system. To this system Nos. 4 and 5 of the above section have also been referred by Dr. von Haast and the writer. The upper beds are the Oamara system of the same authors. The question to be decided is the limit between the two. The green sandstone (No. 5) and the coal shales are generally admitted to be Cretaceous. The geographical distribution of the beds enumerated was briefly described, the gray sandy marl (No. 1), the Amori limestone (No. 4), and the green sandstone having a northerly extension to Cook's Straits, whilst the other beds have been traced to the south only. An examination of the stratigraphical evidence shows that at Weka Pass, and also on the Waipara, the Weka-Pass stone rests on a waterworn surface of the Amori limestone, and near the Pass the former overlaps the latter. The gray marl (No. 2) is evidently unconformable to the lower beds of the Waipara system, whilst at Waipara and Weka Pass it passes down conformably into the Weka-Pass stone. The gray marl also passes up conform-

ably into the Mount-Brown beds. The author concludes that the break in succession is between the Weka-Pass stone and the Amori limestone. The geological evidence is in accordance with the palæontological data. The fossils hitherto found in the Weka-Pass stone (*Voluta elongata*, *Scalaria ro'un la*, *Struthiolaria senex*, *Pecten ho'hstetteri*, *Meom i crawfurdi*, *Schizaster ro'undatus*, and *Flabellum circulare*) are found in other parts of New Zealand in Upper Eocene beds. None of them are known from the Cretaceous Waipara system. The fossils from the gray marl are also in some cases identical with those found in the Mount-Brown beds. The author concluded by giving reasons for not agreeing with Dr. Hector, who classes all the beds mentioned as belonging to one system of Cretaceo-Tertiary age.—On the chemical and microscopical characters of the Whin Sill, by J. J. H. Teall, F.G.S.—A critical and descriptive list of the Oolitic Madreporaria of the Boulonnais, by R. F. Tomes, F.G.S.—On the structure and affinities of the family Receptaculitidæ, including therein the genera *Ischadites*, Murch., (= *Tetragonis*, Eichw.), *Sphærospongia*, Pengelly, *Acanthochonia*, g.n., and *Receptaculites*, Defr., by Dr. G. J. Hinde, F.G.S.—On the Pliocene mammalian fauna of the Val d'Arno, by Dr. C. J. Forsyth Major, communicated by Prof. W. Boyd Dawkins, F.R.S., F.G.S.—Notes on the geology and mineralogy of Madagascar, by Dr. G. W. Parker., communicated by F. W. Rudler, F.G.S. This paper commenced with a sketch of the physical geography of the island of Madagascar. A central plateau from 4000 to 5000 feet high occupies about half the island, rising above the lowlands that skirt the coast, and from this plateau rise a number of volcanic cones, the highest, Ankaratra, being 8950 feet above the sea. With the exception of certain legends, there is no record of a period when the volcanoes were active: two such legends were given. The known volcanic cones were enumerated. They extend from the northern extremity of the island to the 20th parallel of south latitude. Beyond this, granite and other primitive rocks occur as far as lat. 22°, south of which the central parts of Madagascar are practically unknown to Europeans. Some crater-lakes and numerous hot and mineral springs occur. Earthquakes are occasionally felt in the island, most frequently in the months of September and October. The shocks are generally slight. Only a single trap-dyke is known near Antananarivo. The hills ar und this city are of varieties of granite (? granitoid gneiss). The general direction of the strata is parallel to the long axis of the island. Marine fossils have been found by Rev. J. Richardson and Mons. Grandidier in the south-west part of the central plateau. These fossils are referred by the last-named traveller to the Jurassic system. Remains of *Hippopotami*, gigantic tortoises, and an extinct ostrich-like bird have also been recorded. North and north-west of the fossiliferous rocks, between them and the volcanic district of Ankaratra, sandstone and slate occur. North of this volcanic district again is a tract of country in which silver-lead (mixed with zinc) and copper are found. Near the north-western edge of the central plateau are granitic escarpments facing northwards and about 500 feet high. Some details were also given of valleys through the central plateau, and of lagoons within the coral-reefs on the coasts. To these remarks succeeded some details of the physical features exhibited by the province of Imerina as seen from Antananarivo.—Notes on some Cretaceous Lichenoporidæ, by G. R. Vine, communicated by Prof. P. Martin Duncan, F.R.S.

Edinburgh

Royal Society, July 7.—Robert Gray, Vice-President, in the chair.—Prof. James Thomson gave a geometrical solution of the problem: Given a number of points moving Galilei-wise, from their relative positions to determine a reference-frame such that the motions relatively to it may satisfy the condition.—Prof. Tait gave a quaternion solution of the same problem.—Prof. Geikie read a paper on the occurrence of drifted trees in beds of sand and gravel at Musselburgh.—Prof. Tait gave a solution of the problem: To determine the number of different ways in which a given number may be divided, no part being less than 2 or greater than one-half the given number.—Prof. C. Michie Smith gave a communication on the green sun and associated phenomena.—Mr. P. Geddes read the 5th part (psychological) of his paper on analysis of the principles of economics.

Sydney

Linnean Society of New South Wales, May 28.—Prof. W. J. Stephens, M.A., F.G.S., in the chair.—The following papers were read:—New Australian fishes in the Queensland Museum, by Charles W. De Vis, M.A. This, the first of a series of papers descriptive of rare and new fishes in the Queensland Museum, is confined to the *Percidæ* only. Twenty-three species are described and four new genera, viz. *Herops*, allied to *Priacanthus*; *Homodemus*, a fresh-water fish approaching *Dules*; *Auristhes*, of doubtful affinity; and *Hephestus*, a fresh-dusæ vegetable-feeding fish resembling *Lobotes*.—The Hydrome-water of Australia, part iii., by R. von Lendenfeld, Ph.D. The Australian Hydromedusæ are here described which belong to the author's family *Blastopolypidæ*. To the species described by former authors, which are enumerated with references, several new ones are added, some of which are of greater morphological interest, particularly *Diphosia symmetrica*, nov. sp., which produces perfectly bilateral symmetrical female Gonangia. The number of species is exceedingly great. As far as some of the sub-families of this group are concerned, no other shore is inhabited by anything like such a number and diversity of forms as ours.—On the geographical distribution of the Australian Medusæ, by R. von Lendenfeld, Ph.D. The distribution of the Medusæ, or at all events of the large Rhizostomes, is shown in this paper to be entirely controlled by the ocean currents. Consequently, where the currents are permanent the range of a species can only extend in one direction.—The digestion of sponges, ectodermal or entodermal?, by R. von Lendenfeld, Ph.D. The earlier experiments, which were made to ascertain where the digestive organ of the sponge is situated, showed such different results, that the author made a series of experiments on the subject two years ago in Melbourne, and was by the help of these enabled not only to show with a large degree of probability where and how the digestion was effected in the sponge which he experimented on, but he was also enabled by these experiments to find out the cause of the great difference in the results attained by former observers. The experiments were carried on with carmine powder mixed with the water of the aquarium in which the sponge was kept. The results the author arrived at were taken up by the recent authors on sponges at home; and the second part of the question, viz. to which embryonic layer the epithelia belonged which, according to the author's researches, absorbed the food, was extensively discussed. The present paper gives an abstract of this interesting discussion, and there are also a few additions to the author's former statements.—Remarks on the coincidence of the eruption in the Straits Settlements and the red sunsets, by R. von Lendenfeld, Ph.D.

Paris

Academy of Sciences, July 15.—M. Rolland, President, in the chair.—On Newton's rule for finding the number of imaginary roots in numerical algebraic equations, by M. de Jonquières.—On the equation in matrices $px = xq$, by Prof. Sylvester.—Second memoir on the treatment of wheaten flour, by M. Balland.—Observations of the solar protuberances made at the Royal Observatory of the Collegio Romano during the year 1883, by M. P. Tacchini.—On a lunar halo observed at Rome on the night of July 4, by M. P. Tacchini.—On a theorem in mathematical analysis of M. Fuchs, by M. H. Poincaré.—On the electrical conductivity of distilled water and of ice, by M. G. Foussereau. The author infers that under certain conditions the observation of electric resistance may supply a delicate means of testing the purity of water, and determining the slow chemical phenomena produced in liquids.—On the purification of methylic alcohol, by MM. J. Regnauld and Villejean.—Account of a deposit of saltpetre in the neighbourhood of Cochabamba, Bolivia, by M. Sacc. An analysis of this vast deposit, which is large enough to supply the whole of the world with nitrate of potash, yields the following results:—

Nitrate of potash	60·70
Borax, with traces of salt and water	30·70
Organic substances	8·60
	100·00

The author concludes that the saltpetre is the result of the decomposition of an enormous deposit of fossil animal remains.—On the action of coffee on the composition of the blood and the digestive functions, by MM. Couty, Guimaraes, and Niobey. From their experiments the authors conclude that coffee acts beneficially in stimulating the consumption and digestion of the nitrogenous elements in the food.—Note on the perception of the successive chromatic differences on luminous surfaces, by M. Aug. Charpentier.—Note on the topographic distribution of the secondary

processes of decay following on destructive lesions of the cerebral hemispheres in man and some other animals, by M. A. Pitres.—Report on the chief results of the Finnish Polar Expedition of 1883-84, by M. Selim Lemström.

BERLIN

Physical Society, June 13.—Prof. Lampe spoke on the subject of a hypothesis respecting the formation of the solar system set up by M. Faye in place of Laplace's hypothesis. According to M Faye's theory, in the original uniform nebular mass, vortices were formed which gave rise to the existence, first of the middle planets, and then, ultimately, of the outer planets. This hypothesis was advanced as an explanation of the fact that the moons of Uranus and Neptune revolved in a direction opposite to that of the sun, the planets, and the other moons, a fact which was not accounted for by Laplace's theory. Only a brief communication, however, had yet been published of M. Faye's hypothesis, which, too, appeared to betray a number of lacunæ.—Dr. König called attention to the investigations that had hitherto been prosecuted on the subject of complementary colours, that is of those pairs of homogeneous spectral colours which, being blended together, produced a white appearance. Regarding the number of such pairs contained in the spectrum there had in all been three distinct experiments made—one by Herr von Helmholtz about the beginning of the '50's, another by Herr Schelske, and a third by Herren von Kries and von Frey. Having described the methods which had been followed in these different experiments, Dr. König proceeded to the results that had been severally arrived at, dismissing, however, without further consideration those attained by Herr Schelske as being all too defective in precision. Herr von Helmholtz had found in the spectrum seven pairs of complementary colours for his eye, Herr von Kries thirteen, and Herr von Frey, who had made use of the same apparatus as that adopted by Herr von Kries, likewise thirteen. The results represented in an arbitrary scale by the two last observers Herr König had converted into undulatory lengths, and, as in the case also of the results attained by Herr von Helmholtz, had exhibited them graphically. By drawing up the undulatory lengths of one spectrum as abscissæ, and those of the other as ordinates, he obtained for the complementary colours of the three observers certain points which, being connected together, yielded a curve of the complementary colours. While now the complementary colours were peculiar for each eye, the three curves of the complementary colours were, on the other hand, very approximate and similar to each other. Herr König then brought forward a few more considerations on complementary colours for monochromatic, bichromatic, trichromatic, and tetrachromatic eyes, demonstrating how, in the case of monochromatic eyes, there could be no question whatever of complementary colours. In the case of bichromatic eyes, on the other hand—eyes, that is, distinguishing only two ground colours, "colour-blind" eyes, as they were usually denominated—the complementary colours on their graphic representation formed quadratic surfaces lying outwardly from the neutral point. In the case of trichromatic eyes, again, they formed two curves, as was deduced from the observations, while, finally, in the case of the tetrachromatic eye, the complementary colours likewise formed curves, the curves marking the perception of the separate ground colours ranging over the whole spectrum. If, however, this last phenomenon was wanting, then complementary colours appeared only when the sectional point of the first and second curve corresponded with a shorter undulatory length than the region of the fourth curve, and the sectional point of the third and fourth curve corresponded with a longer undulation than the end of the first curve. If this condition were not fulfilled, complementary colours could not appear, a fact which would seem to militate against the possibility of a tetrachromism, that is of the existence of four ground colours.

Physiological Society, July 4.—Prof. Munk spoke on the extirpation of the cerebrum in rabbits. After a short historical survey of Prof. Christiani's and his own publications on the functions of the cerebrum, the speaker summed up the difference between his results and those of Prof. Christiani in the statement that in his most successful experiments, after removing the cerebrum, he observed in rabbits, just as in other vertebrates, birds and frogs, a state of depression lasting for a longer or shorter period, to as long as several hours, a state in which they lay apathetically, taking and keeping whatever position might be imposed on them. From this state they recovered to go through, first of all, interrupted and apparently spontaneous movements, which yet, however, on closer inspection proved to be reflex movements. These, again, were followed by a quickened reflex excitability, which finally was succeeded by compulsory movements, a kind of running stage, which, twenty-four to fifty hours after the operation, issued in the death of the animal. Prof. Christiani, on the other hand, after removing the cerebrum, in no case observed a state of depression such as that above referred to, but his excerebrated rabbits all acted like normal ones: they moved about, sprang, ran, &c., during the first twelve hours at least after the operation, which he exclusively observed. Prof. Munk then scrutinised the methods of the operation, pointing out certain minute differences between them, which he subsequently turned to account in explaining how the results deviated so widely from each other. These differences in the execution of the same operation consisted in the fact that he (Prof. Munk) made the section at a somewhat further distance (from about 1 to 2 mm.) from the optic thalami than did Prof. Christiani, and that he had made use of a knife while Prof. Christiani used the handle of a knife to separate the crus cerebri. In explanation of the phenomena observed, Prof. Munk, by means of sections and searching examinations of the brains operated on, established that the depression which at first ensued was the direct effect of the removal of the cerebrum, and that the succeeding reflex irritability and compulsory movements, the latter of which lasted till death, were due to an inflammation which extended from the surface of the incision to the cerebral ganglia, and, quite in accordance with the occurrence of the running stage, appeared sooner or later, progressed with more or less rapidity, and ultimately caused death. Prof. Christiani in his experiments did not observe the first stage, that of the exhaustion of the animal, which resulted from the extirpation of the cerebrum, but only the second or running stage following immediately on the operation, because in his procedure the severer irritation of the surface of the incision, together with the bleeding, led at once to inflammation of the cerebral ganglia, that in the case of Prof. Christiani's experiments lay so much nearer the surface of the incision.—Prof. Christiani in replying to Prof. Munk's address, rebutted the latter's interpretation, maintained in all points the validity of the results he had arrived at, and referred to a more complete publication, which was shortly to appear, in which he would prove his assertions, as well as refute the objections that had been raised.

FORESTRY

Introduction to the Study of Modern Forest Economy, and *Forestry in Norway, with Notices of the Physical Geography of the Country*. By John Croumbie Brown, LL.D. (Edinburgh: Oliver and Boyd, 1884.)

EVERYTHING connected with forestry is especially attractive just now when so much attention is being drawn to the subject in its very varied aspects by the Exhibition at Edinburgh. Dr. J. C. Brown is one of the most voluminous writers we have on forest matters; his pen indeed is scarcely ever at rest, for he has told us about forests and forest management in various parts of the world, both in ancient and modern times, and now he publishes just at an opportune moment two little books the titles of which are given above. The first of these he tells us is issued in accordance with, and in discharge of, obligations imposed by a resolution passed on March 28 last year by a "scientific, practical, and professional" assemblage presided over by the Marquess of Lothian for the purpose of furthering "the establishment of a national School of Forestry in Scotland," and the promotion of "an International Forestry Exhibition in Edinburgh in 1884," the last of which is now being realised, but the former has yet to be accomplished, we hope, however, at no distant date.

Dr. Brown's first book commences by defining what a forest is, and he then goes on to point out that "in the conservation, culture, and exploitation, or profitable disposal, of forest products considerable differences of practice exists," as, for instance, the preservation of game in this country, while on the Continent the wood is the primary object. "In Britain," he says, "we hear much of arboriculture; on the Continent we hear much of sylviculture; the former refers to woods and plantations, the other term speaks of woods and forests; in the one case the unit is the tree, and the wood is considered as the collection of trees; in the other the wood is the unit, and the trees are considered only as the constituent parts. In the former attention is given primarily to the sowing and planting, and pruning it may be, and general culture of the tree; nowhere perhaps has this arboriculture been carried nearer to perfection than it has been in Britain, and the effects produced by the resulting woods are wonderful. In the latter, attention is given primarily to the wood or forest as a whole, capable of yielding products which can be profitably utilised; and the result generally is to produce a much greater proportion of fine trees than does even the arboriculture which has been referred to. And not less different is the exploitation of woods in Britain and on the Continent. In Britain the pecuniary return obtained from woods is considered a secondary matter in comparison with the amenity and shelter which they afford; but on the Continent the materials or pecuniary product, or other economic good, is made the object of primary importance."

This opens the subject of forestry in its widest aspect, and Dr. Brown naturally draws from it a moral on the necessity of forming the much talked of British School of Forestry. The book is divided into three parts, in the first of which the successive chapters treat of the following subjects: Ancient Forests of Europe, the disappearance of European Forests, the evils which have followed their destruction, scarcity of timber and firewood, droughts, floods, landslips, and sand drifts. The second part is devoted to the consideration of "Elements of Modern Forest Economy," under which head we find chapters on Forest Conservation, Replanting or Reboisement, as Dr. Brown prefers to call it after the French usage; Exploitation or Management, Sartage and Jardinage, or Clearance and Selection, &c., concluding this part with a chapter on the study of Pathology. The third part is simply a short notice of modern forest conservancy in general. All these points are of extreme importance in a well-organised system of forest teaching, and under each head Dr. Brown brings together a quantity of matter which, besides being of a practical character, and consequently valuable, is also interesting reading. He possesses the power in an eminent degree of weaving into one uniform fabric what has been said by various writers on the subject that he has so much at heart, for Dr. Brown's books contain long and numerous quotations, through which it will not be necessary to follow him. On the study of pathology, however, as one of the branches in the curriculum of a forest officer's education, we entirely agree with him as to its great importance. It should indeed be equally imperative that a young forester should know something of the nature of the diseases with which the trees under his care are liable to be attacked, as that he should be acquainted with the structure, constitution, and habits of those trees, so that he may be enabled, if occasion requires, to cope with their diseases, and if possible save the victims from premature decay. For this reason a pathological museum should be attached to every forest school, and specimens might be continually added to it by preserving those that might be brought into the school for determination. Such a museum indeed is referred to by Dr. Brown in the following paragraph:—"In the Museum of the Prussian Forest Institute at Eberwalde the impression produced upon the mind of the visitor is that there are there specimens representative of every disease to which trees are heir; specimens exhibiting the progress of the disease from the attack to the consummation; and, hard by, the bark, the wood, the insect, or the parasitic herb or fungus by which it has been induced, the insect and the fungus being exhibited under all the transformations through which they pass; while specimens of the effects of lightning and other physical causes of the decay or destruction of trees are not lacking. And similar collections sufficient to afford facilities for the study of the diseases of trees and of means of preventing or of remedying the evils done are to be found in many other similar institutions." Dr. Brown concludes his first book with a sketch of the curriculum of the Spanish School of Forestry, which includes a wide range of subjects in mechanics, physics, acoustics, heat, optics, electricity, meteorology, chemistry, natural history, including botany and zoology. "The instruction is given (1) by oral lectures and lessons in drawing by the professors; (2) by written exercises, calculations, and analyses on the subjects embraced by these lectures; (3) by the detailed study of the animals, rocks, plants, and forest products which constitute the collections and adjuncts of the establishment; (4) by the practice of topography, land-surveying, the

study of natural history, and of mountains in the field; (5) by excursions to the plantations and mountains."

With regard to the status of forest officers in different parts of Europe they are described as taking rank with military men and other Government officers of recognised social position, and having in many instances an official uniform and a higher salary than is accorded to military officers, by way of compensation for the monotonous life they are called upon to lead in the forests, which often has a depressing influence—"day after day, month after month—trees, trees, trees everywhere, trees and shade, trees and shade—shade that reminds one of the expression '*the valley of the shadow of death.*'"

"Forestry in Norway" is a book of a different character from the preceding. It treats of the general features of the country in its various aspects, with especial regard of course to its arboreal vegetation, and the effects of temperature, rainfall, rivers, lakes, mountains, valleys, &c. The book is for the most part very pleasant reading.

In Chapter IV., under the head of Geographical Distribution of Trees in Norway, Dr. Brown shows that he has made himself acquainted with the modern literature of the subject, especially with the well-known report and maps prepared by Dr. F. C. Schubeler, Professor of Botany in the University of Christiania. From this and from the numerous other works cited the conclusion is drawn that the true forests of Norway are composed almost entirely of the Norway spruce fir (*Picea excelsa*, Link.) and the Scotch fir (*Pinus sylvestris*, L.), though some other trees, as the elder, beech, and oak, are found forming little woods. We must here point out that nearly the whole of this chapter requires careful editing. There is no excuse for the retention of old and exploded names, still less perhaps for absolute mistakes. On p. 39, for instance, it is stated that the Norway spruce is generally known as *Abies communis*, a name under which very few indeed would know it except those well versed in the synonymy of the plant. On the same page *Millaw* is printed for Miller, *Lank* for Link; and a page or two further on, the Norwegian birch is referred to *Betula odorata*, Bechet, when it should be *B. alba*, L. Again on p. 45 we are told that two species of oak "are found growing wild in Norway, the sessile-fruited oak, *Quercus robur*, W., and the common oak, *Q. pedunculata*, W." The fact is that the sessile-fruited oak is *Q. sessiliflora*, Sm., and the pedunculated oak, *Q. pedunculata*, Ehr., both of which are now placed by most modern authorities under the one name of *Quercus robur*, L. Similar instances occur further on, as well as misspellings, all of which could be easily rectified, and the book made more trustworthy.

The general readable nature of the bulk of the book will no doubt cause it to be read by those into whose hands it may fall, whether they are specially interested in forestry or not, and will thus form one means of promoting the extended use of the volume.

LENSES

Lenses and Systems of Lenses. By Chas. Pendlebury, M.A., F.R.A.S., Senior Mathematical Master of St. Paul's. (Cambridge: Deighton, Bell, and Co., 1884.)

WE are glad to welcome at last an English book on this subject, on which up to the present but little has been written in our language. An abstract of Gauss's paper in Taylor's *Scientific Memoirs*, and a paper by Maxwell in the second volume of the *Quarterly Journal of Mathematics* form, so far as we are aware, the main English literature of the subject. Of course since the time of Gauss foreign writers have used it freely: Listing, Helmholtz, and Carl Neumann in Germany, Verdet and others in France, have introduced it with more or less modification into their works. We would suggest that a list of books and memoirs on the subject would form a valuable addition to Mr. Pendlebury's book. The author gives frequent references in footnotes to books or papers from which he has drawn information, but a complete list would be a great help to others studying the subject. The method itself is very elegant and attractive, though somewhat barren of results; perhaps this is the reason why it has been neglected in England. It enables us to obtain a beautiful solution of the problem to a first approximation when all the rays make but small angles with the axis, but refuses to help us further.

The book before us is clear and well written, though perhaps unnecessarily long. Mr. Pendlebury has three chapters successively on refraction at a single surface, at two surfaces, and at any number of surfaces. This would be very well for a student who was supposed to begin the study of optics with this book, but such a student is hardly likely to exist; and one who has read the ordinary text-books on the subject could easily follow at once the reasoning of the most complicated case, and might be left to deduce the others so far as they differ from it as corollaries.

Referring, however, to some points in the book, we think that in Fig. 4 it would have been better to take as the standard case one in which the points X and X′ both lie to the same side of A, the case usually considered in text-books on optics. This would have obviated the necessity of having to put a negative sign to the symbol u in the algebraical work. Attention also might with advantage be called to the point that one of the two focal distances is negative.

Again, a difficulty occurs when we compare the results of Sections 67 and 74; in the one we have

$$\frac{1}{v} - \frac{1}{u} = \frac{1}{f},$$

while, using the same notation, the results of the other may be written

$$\frac{1}{v} + \frac{1}{u} = \frac{1}{f}.$$

The explanation, of course, is that Fig. 18, from which the last result is deduced, is not drawn for the standard case of a lens forming a virtual image of an object. There is another small point of arrangement which it seems to us might be slightly modified with advantage; we would draw a rather more definite line between the analytical and geometrical methods of treating the subject.

If we assume that a pencil of rays diverging from a point will, after refraction, pass through a point, we can prove geometrically the existence of the principal points, the focal points, and the nodal points. We cannot, however, without analysis, find the position of these points in terms of the curvatures and distances between the various refracting surfaces.

Again, if we assume the position of the focal and

principal points, we can find geometrically the position of the image of any point after refraction through the surface. This we may describe as the geometrical treatment of the subject.

By the aid of analysis we can show that there is, to the degree of approximation to which we go, a point image of any point, and we can find in terms of known quantities the positions of the cardinal points of the system and the relation between a point and its conjugate focus. Mr. Pendlebury adopts both methods indiscriminately; it seems to us that it would have been better to have kept the two somewhat more distinct.

A short account of the paper of Maxwell to which reference has been made, "On the General Laws of Optical Instruments," would form a valuable addition to the book, and may, perhaps, be included when the author extends it, as he hopes to do, so as to cover a wider area in the field of geometrical optics. At present the field is open to him, and a book on the whole subject as good and interesting as "Lenses and Systems of Lenses" is greatly needed. R. T. G.

OUR BOOK SHELF

Fuel and Water. Translated from the German of Franz Schwackhöfer, by Walter R. Browne, M.A. (London: Charles Griffin and Co., 1884.)

Mr. Walter R. Browne has made a very good translation of a book written for the German students of agriculture in Vienna. He has added a clever sketch of the mechanical theory of heat as an introduction. The English of the translation is remarkably good and clear, and the original treatise has been written by a competent man. The translator in his preface appeals to manufacturers and users of steam on a large scale; but the work is much too scientific for them, dealing not with the various forms of boiler now in the market, but rather with the general principles on which boilers should be constructed. On the other hand I fear that the information given is in many parts not full enough for the engineer, and we frequently find data given such as will be of more value to the German than to the English reader. The chief physical formulæ relating to heat and applicable to practical questions connected with engineering are clearly stated, but the comparison of results deduced from these formulæ with the results derived from actual experience is rather sparingly made. The third chapter, which is headed "Heating Apparatus," treats of the furnace and its management. The author gives the results of some actual experiments as to the loss of heat in the chimney, in the ash-pits, in priming water, and by conduction and radiation. He also gives an experiment with what is called an economiser. This chapter seems to me one of the best in the book. Altogether, I think the work is one which may in many parts be profitably consulted by those engineers who desire to compare theory with practice.

Fleeming Jenkin

The Elements of Euclid. Books I. to VI. With Deductions, Appendices, and Historical Notes. By J. S. Mackay, M.A. (London: W. and R. Chambers, 1884.)

This text-book has been compiled at the request of the publishers, and the event shows that it was by a "happy thought" their choice of an editor fell upon Mr. Mackay, the Mathematical Master of the Edinburgh Academy. Of it we have nothing to say but what is good. This praise is not so much for the text, for others have done well in this direction. Still even here Mr. Mackay has shown great judgment and skill in his selection of proofs. The text is in the main that of R. Simson's well-known editions, and no change has been made in Euclid's sequence of propositions, and no violent change in his modes of proof.

But what we particularly like are the carefully prepared historical notes, which take the form of footnotes or of fuller paragraphs in the six appendices. Mr. Mackay remarks, "It would perhaps be well if such notes were more frequently to be found in mathematical text-books: the names of those who have extended the boundaries, or successfully cultivated any part of the domain, of science, should not be unknown to those who inherit the results of their labour."

We regret that though authors have before expressed themselves to similar effect, yet few have had the inclination or leisure to act as our present author. He has had to curtail his material, but what he gives us shows that he is well qualified by the extent of his reading to satisfy this want.

We note here that recent French mathematicians are in the habit of attributing the first use of the word "orthocentre" (which Mr. Mackay ascribes to Dr. W. H. Besant) to Dr. Booth; in so doing they are certainly in error, as Dr. Booth himself, in the second volume of his "New Geometrical Methods" (p. 261), says "the point has been called by some geometers the *orthocentre.*" What he may lay claim to is his calling what is now often called the *pedal* triangle the *orthocentric* triangle.

The figures are admirably drawn and are quite a feature of the book; they deserve the editor's commendation when he thanks Mr. Pairman for the "excellence of the diagrams."

This edition is well suited for the geometrical student, and, at the same time, its cheapness puts it within the reach of all who wish to study "Euclid."

Traité Pratique d'Analyses chimiques et d'Essais industriels. Par Raoul Jagnaux. (Paris: Octave Doin, 1884.)

The purpose and character of this little book is best indicated by the saying of Berzelius which heads the author's preface: "Le meilleur mode d'analyse est celui qui exige le moins d'habitude chez l'opérateur." The book is mainly intended for the use of the chemical engineer and the metallurgist, and the methods of analysis described are essentially "works-methods," in which rapidity of execution is a very important consideration. Many of these methods are new, and have been devised partly by M. Hautefeuille, and partly by the author. We would especially note those depending upon the precipitation of such metals as zinc, copper, nickel, and bismuth as oxalates, whereby the formation of gelatinous precipitates, difficult to wash, is avoided. The book contains a large number of analytical results as evidence of the validity of the methods employed; many of these analyses, such as those of aventurine glass, garnierite, sylverine, are valuable as illustrating the composition of substances which are not frequently examined. T.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Relation between the B.A. Unit and the Legal Ohm of the Paris Congress

At a meeting of the Electrical Standards Committee of the British Association held on Saturday, June 28, the following resolution was carried:—

"That for the purpose of issuing practical standards of elec-

trical resistance, the number of B.A. units adopted as representing the resistance of a column of mercury 100 centimetres in length, one square millimetre in section, at a temperature of 0° C. be ·9540."

It follows from this that the legal ohm of the Paris Congress, which is defined as the resistance of such a column 106 cm. in length, contains 1·0112 B.A.U., while the B.A.U. contains ·9889 legal ohm. Thus resistances which are expressed in terms of B.A. units may be reduced to legal ohms by multiplying by ·9889, while makers and others who have a standard B.A. unit can construct a legal ohm by making a coil equal to 1·0112 times that unit.

A resolution of the nature of the above was rendered necessary by the fact that the legal ohm is defined in terms of the resistance of a column of mercury, while the resistances in use in England are B.A. units. The relation between the two has been determined by different observers with slightly different results. The Committee hope to secure uniformity in the resistances sold to the public as legal ohms, by stating the number they intend to adopt for the purpose of issuing standards.

R. T. Glazebrook,
Secretary Electrical Standards Committee of the British Association

The Yard, the Metre, and the Old French Foot

The ratio of the metre to the yard can scarcely be said to be known with certainty at the present day. The latest and most exhaustive investigation of this question is due to Prof. W. A. Rogers of Cambridge, Mass. The value which he assigns to it (pending a final and authoritative comparison of the "Mètre des Archives" with its chief representative, by the International Commission of Weights and Measures) is—

39·37027 : 36.

This ratio is very nearly identical with the much simpler one—

35 : 32,

the error of which is less than 1 in 8000. If we disregard this error, the conversion of yards into metres can be effected with the greatest ease by the following arithmetical process. Thus—

Given	35 yards or	39·37027 yards	
Subtract 1/10th	− 3·5	− 3·937027	
Add 1/7th	+ ·5	+ ·5624324	
Results	32·0 metres	35·9956754 metres	
		Error − ·0043246	

By a singular piece of good luck, this error, small as it is, may be entirely removed by one more easy approximation: for dividing the last quotient by 130 gives + ·0043263—where the outstanding disagreement is less than a unit in the last given figure. Hence, if we wish for a closer conversion than will be given by the terms 1, $-\frac{1}{10}$, $+\frac{1}{7}$ (of the last), we have only to add further, $+\frac{1}{130}$ (of the last) to obtain the utmost accuracy at present possible.

The converse operation—to convert metres into yards—is not quite so short and easy in the closer approximation. The following shows the approximate and the more exact conversion:—

	Ex. 1	Ex. 2
Given	32 metres	36 metres
Add 1/10th	+ 3·2	+ 3·6
Subtract 1/16th	− 0·2	− 0·225
,, 2/100ths ...	—	− ·0045
,, 1/20th	—	− ·000225
Results	35·0 yards	39·370275 yards

The fact is, almost any conversion may be performed in some such way, in three or four operations; and it was not for the sake of the rigorous ones that this note was written, so much as to bring into notice the very close and useful approximation represented by the ratio 32 : 35.

By way of applying the rules usefully, we may take as examples:—To find the equivalent of a kilometre in yards, and of a mile in metres. Thus—

1000 metres	1760 yards
100	− 176
6·25	+ 25·14286
·125	+ ·19341
·00625	
Answers 1093·61875 yards ...	1609·3363 metres

Here we see that the approximate ratio 32 : 35 entails an error of only 0·131 yard (or less than 5 inches) in one kilometre; or of 0·193 (or less than 2) decim. in one mile, so converted.

The old French foot, the sixth part of the toise—the famous "Toise of Peru"—survives now practically only in the Prussian toise, so far as that is not superseded by the metre. Whatever may be its present range, the ratio of the old French foot to the present English foot is curious. I believe it may be expressed, within the limits of error of the relation so far as can now be known, by the fraction 389/365. That is to say, the excess of the former is 24/365 × the latter, the two components of which fraction are such as may easily be remembered when once the coincidence has been noted.

Collingwood, July 25

Fireballs

In reference to the phenomena of fireballs the following notes may be of interest. Last year, in July, I was residing on Naphill Common, Buckinghamshire. About midday, during my absence at Oxford, a violent thunderstorm broke over the district, and appeared to extend from Oxford to London. On returning I found that the house had been struck by lightning, apparently in two places. One chimney was knocked in through the roof, the debris partly filling up my room. The kitchen chimney had also been visited, the lightning breaking some of the brickwork of the hearth, and passing a person cooking at the fire; two or three others were in the house at the time, but no one was hurt. On carefully examining the marks left, I found that a door in a room adjoining the one above-mentioned had been split, and some iron knobs knocked off and broken, the screw nails being removed out of the wood, and a large hole several feet square made in the side of the house. From examination of the outside of the wall at the foot of the kitchen chimney, the bricks showed displacement opposite the marks inside at the hearth. I believe a tree was struck, and a water-trap or cesspool shifted out of position. Some men using a reaping machine in a neighbouring field stated that they knew the storm was coming by the fire playing about the blades of the machine. A boy who had been near at the time said that he saw a large ball of fire fall on the house, which it seemed to enter; it then reappeared, and passed into the meadow. I therefore think it likely that the damage done to the rooms and side of house was due to the electric development called a fireball.

Glasgow W. J. Millar

The Swallowing of one Snake by another

As the author of the article "A Cannibal Snake" (Nature, July 3, p. 216) wishes to know whether an instance similar to that recorded by him has ever before been brought to notice, I feel bound to publish an occurrence which I witnessed many years ago, and of which I have often told, without ever putting it into writing. During the summer of 1857 I lived in the environs of Washington; as an amusement, snakes were kept in cages. Sometimes, in the evening twilight, when toads and frogs appeared on the garden paths we used to feed the snakes with them. The usual habit of the snakes was to seize the toad wherever the jaws happened to strike, and to move them afterwards along the body of the victim, so as to begin the process of swallowing from the head. Once I threw a toad into a cage containing two of the common water-snakes of that region (*Nerodia sipedon*, if I recollect right, is the scientific name of the species). Both seized the toad at the same time; the one near the head began at once to swallow; the other put its jaws in motion as usual, in order to get at the head, but in doing this it reached the head of its comrade, and *began to swallow that, as well as the toad*. This went on for some time, until about three-quarters of the one snake were ingulfed within the other. Then the snakes separated again, the swallowed one coming out covered with slime, but apparently unhurt and as lively as ever. It lived a long time afterwards. The snakes were of about equal size, and, as far as I remember, from 2½ to 3 feet long. I suppose that it was the swallowing snake, and not the swallowed one, that kept the frog, but I do not think I ascertained the fact at the time. The whole performance lasted a few minutes only.

Heidelberg, Germany, July 27 C. R. Osten Sacken

The Red Sunsets

I note in Nature of July 3 (p. 229) an abstract of a communication of M. Gay to the Paris Academy of Sciences, made

on June 23, in which he suggests a connection between the red sunsets and the frequent rains. During the latter half of the past winter the rains were incessant in the Atlantic States of America, and the writer suggested that they were due to the volcanic dust in the atmosphere, in a letter published in the *Philadelphia Public Ledger* of February 23. In a subsequent issue, March 8, he called attention to Dr. Aitken's researches. Subsequently Prof. Heilprin, of the Philadelphia Academy of Natural Sciences, offered a similar suggestion.

Philadelphia, July 16 CHAS. MORRIS

THE SALTNESS AND THE TEMPERATURE OF THE SEA[1]

PROFESSOR DITTMAR'S researches, an account of which forms Part I. of this volume, have finally proved that, so far as the most refined analysis can go, the mixture of salts dissolved in ocean water has attained a state of chemical equilibrium. But, although there is constancy of proportion between the various salts, the ratio of the total salts to the water varies considerably in different parts of the ocean.

The great evaporation in the dry tropical areas and the removal of water by freezing in the Polar seas tends to increase the salinity in these places, while in the tropical zones of continual rain and in the Polar fringes where the icebergs melt, there is constant dilution going on. The determination of the salinity at different places and depths is of great oceanographic importance, and the problem of finding the salinity has been attacked in various ways. The most simple and straightforward is to evaporate a weighed portion of the water to dryness and weigh the residue, but this cannot be done without chemical change taking place. The magnesium chloride present decomposes with the water into magnesia and hydrochloric acid, and all the carbonic acid of the carbonates is driven off. Gay-Lussac showed long ago how to avoid the error due to the dissociation of magnesium chloride, but no means have yet been suggested for taking account of the carbonates in a total salt determination. Direct weighing being thus found inexpedient, the next best method would appear to be to find the exact amount of any one element present, and by means of a table of complete analysis, taking advantage of the constancy of composition of ocean salts, to convert that into the salinity by multiplication with a constant factor. This is the method which Prof. Dittmar prefers, and for the purpose he estimates the chlorine or rather the total halogen by means of his refinement of Volhard's process. When the salinity of water has to be determined at sea, this delicate method cannot be conveniently employed, and it has been customary hitherto to measure the specific gravity of the water very carefully and afterwards to reduce the results to salinities. An attempt has been made with considerable success in the United States to substitute the determination of the refractive index of water for that of the density, and thence to deduce the salinity by a formula. This method is pre-eminently adapted for use at sea, but it appears not to possess the necessary delicacy.

The only method by which the specific gravity of a fluid can be ascertained on board ship is by means of hydrometers, and as the extreme values for sea-water are, according to Mr. Buchanan, 1·02780 and 1·02400, apparatus of great delicacy must be employed. A very delicate glass hydrometer was used on the *Challenger*, yet in spite of its fragility and the thousands of observations that Mr. Buchanan made with it in all weathers, he succeeded in carrying the one instrument which he had used during the entire voyage back to this country unbroken. His description of the hydrometer is as follows:—

"Preliminary calculations showed that convenient dimensions would be about 3 mm. for the diameter of the stem and about 150 c.c. for the volume of the body, and from 10 to 12 cm. for the length of the stem. The tube for the stem was selected with great care from a large assortment, and no want of uniformity in its outward shape could be detected with the callipers. The tube for the body of the instrument was also selected from a number, in order to secure such a diameter as would give the instrument a suitable length. In order to provide against accidents, I had four instruments made from the two lengths of tubing. The glass work of the instrument being finished—except that the top of the stem, instead of being sealed up, was slightly widened out into a funnel—the instrument was loaded with mercury, until the lower end of the stem was just immersed in distilled water of 16° C. A millimetre scale on paper was then fixed in the stem, and the calibration carried on by placing decigramme weights on the funnel-shaped top, and noting the consequent depression on the scale. The whole length of the scale was 10 cm., and this portion of the stem proved to be of perfectly uniform calibre. Several series of observations were made in order to determine accurately the volume of any length of the stem. . . . When this operation of calibration was finished, the end of the stem was carefully closed before the blowpipe."

The constants necessary for making a specific gravity observation were all determined with the utmost care. They included the exact weight *in vacuo* of the instrument, the volume of the body, the volume of each division of the stem, and the expansion of the whole instrument for a degree Centigrade. These data were fully tabulated, and in addition tables were made of the total weight when each of a set of brass weights was placed on a small table that could be slipped over the top of the stem. These weights were necessary, as, without them, the stem would require to be of great length in order to serve for waters of different density.

In making an observation Mr. Buchanan always kept the water sample in the laboratory for a night in order that it might have time to attain the temperature of the surrounding air. He then placed about 800 c.c. in a glass jar supported on a swinging table, and immersed the hydrometer in it after ascertaining its temperature exactly. To insure the greatest possible accuracy two readings were frequently made with different weights on the table, the results separately reduced, and the mean taken as the density. The density was calculated in every case by ascertaining the weight of the loaded hydrometer and dividing it by the immersed volume, which is calculated from the temperature and stem-reading.

Prof. Dittmar examined very particularly into the probable error in reading Buchanan's hydrometer, and after a long series of experiments, described in the chapter on Salinity in Part I., he came to the conclusion that the difference between the salinity as calculated by it and by his direct chlorine determinations (*i.e.* $\chi_1 - \chi$ where χ stands for the permilleage of chlorine) amounted to $-·042 \pm \delta$, δ being a variable the chances of which being greater or less than ·06 are equal, and are 4 to 1 in favour of its being less than ·12. The value of χ is usually between 19 and 20.

At first Mr. Buchanan reduced his specific gravities to the temperature of 15°·56 C. by Hubbard's tables, but Prof. Dittmar, in the course of his investigation of "The specific gravity of water as a function of salinity, temperature, and pressure," succeeded in constructing a much better table in which the variation of the coefficient of expansion with the salinity of the water is taken account of, and all Mr. Buchanan's results published in this volume have been calculated by it. A very ingenious graphic method of comparing Hubbard's results with Dittmar's and converting one into the other is given in Plate I. of Part II.

[1] "The Physics and Chemistry of the Voyage of H.M.S. *Challenger*." Vol. i. Part ii. "Report on the Specific Gravity of Ocean Water." By J. Y. Buchanan, M.A., F.R.S.E. Part iii. "Report on the Deep-Sea Temperature Observations obtained by the Officers of H.M.S. *Challenger* during the Years 1873-76." (London: Longmans and Co., 1884.) See NATURE, July 24, p. 292.

In the course of his work Prof. Dittmar hit upon an elegant method of determining densities, which was found to be very satisfactory. He filled a water-bath with a particular sea-water that had been selected as a standard, and kept it at a constant temperature. A specific-gravity bottle was filled with the same water, stoppered, hung in the bath to the balance-pan, and weighed accurately. To compare any number of samples of water it was sufficient to fill up the bottle with the water in question, and again weigh it immersed in the standard. Prof. Dittmar confined himself to making out the relation between salinity, specific gravity, and temperature, leaving the relation of specific gravity and pressure for subsequent treatment by Prof. Tait, whose great chain of experiments on the compressibility of sea-water is now drawing to a close, and the results of which will shortly be published in the *Challenger* Reports. The conclusion Prof. Dittmar comes to is summed up in the formula—

$$\chi = \frac{{}_4S_t - {}_4W_t}{a + bt + ct^2},$$

where χ is the "salinity" or permilleage of halogen; ${}_4S_t$ the specific gravity of sea-water at $t°$ relatively to pure water at 4° C.; ${}_4W_t$ is the specific gravity of pure water in the same way; a, b, and c are constants which have been determined once for all.

In the chapter on Salinity in Part I. Prof. Dittmar gives a table dealing with 300 samples, collected in all parts of the ocean and from all depths. These tables show the position, the depth of the ocean at the station, the depth from which the sample was drawn, the permilleage of chlorine (χ), the mean deviation of the mean χ from the individual results, and the difference between the amount of chlorine as calculated from Buchanan's observations of specific gravity, and as found directly by Dittmar.

Mr. Buchanan gives in his report all his observations classified according to geographical position and depth, and arranged in eighteen large tables. These record the specific gravity of water from all depths in the North and South Atlantic, the Southern Indian Ocean, the North and South Pacific, and the interesting inclosed seas of the Malayan Archipelago. The numbers are simply given as they were observed, only corrected for temperature by Dittmar's table, and all discussion of their oceanographic significance has been deferred until a subsequent occasion.

A series of coloured charts illustrating the bathymetrical and geographical distribution of specific gravity over the whole world and in the individual oceans accompanies the memoir. These are extremely interesting, and in many cases they tell their own story without explanation, though when the full descriptions are published, the value and interest of the plates will be greatly increased. The track-chart of the *Challenger* coloured to show the surface salinity of the ocean, is especially worthy of notice; its details have been filled in, and the whole rendered more complete, by the incorporation of the results of other exploring expeditions.

The great importance of Mr. Buchanan's specific gravity observations will be more readily recognised by the general reader when they are elucidated by the work of Prof. Tait and Mr. Buchan, and treated more generally than is possible in a mere statement of observed figures.

The third part of the volume is devoted to the temperature observations made during the cruise. The nature of the information contained in the curves which make up this part of the work is very concisely put in the editor's introduction:—

"It has been deemed advisable to publish, for the convenience of scientific men, the whole of the deep-sea observations of temperature made during the voyage of the *Challenger*. These are given in detail in the accompanying series of 263 plates, which show the latitude and longitude of the station; the depth in fathoms of the bottom; the depth at which each temperature was taken; the number of the thermometer; the temperature actually observed read to quarter degrees; the error of the thermometer; and the temperature corrected for instrumental error only."

The temperatures have been plotted by Staff-Commander Tizard, and a free-hand curve drawn through the points. From this the "temperature by curve" which is employed in drawing the diagrammatic sections of the ocean showing the bathymetrical arrangement of the isothermals is taken. These sections will be published in vol. i. of the *Challenger* narrative, and to the general reader they will present a much more intelligible idea of the distribution of oceanic temperature than can be given by the study of tables of figures or curves for separate stations. The separate station curves are, however, of the utmost value to any one who wishes to make a detailed study of ocean temperatures. With a direct view to such a purpose the curves have been drawn with rigid adherence to the numbers in the observation books, even the most obvious cases of observational error being left uncorrected; for the specialist can easily discover and correct them himself, and no one else will notice them.

The temperature observations, like the specific gravity observations, form a rich mine of material with which good work may be done. It is shown by a glance at the charts that there are areas in the ocean of great salinity and areas of great dilution; it is shown that the pressure increases uniformly with the depth; it is known that the surface temperature of the water varies greatly in different latitudes, and that, as the depth increases, the temperature decreases, at first very rapidly, but after the first few hundred fathoms with increasing slowness, until at the bottom the temperature of the open ocean is everywhere the same, between 34° and 35° F.; it is known also that in inclosed seas, or in those where there are submarine barriers cutting them off from the rest of the ocean, the temperature assumes a constant value in its descent, and sometimes the bottom is nearly 20° F. warmer than that of the ocean at the same depth a few miles distant; but this is all that is known. It is evident that there must be an ocean circulation on a magnificent scale going on, a gradual onward sweep of the whole mass of the water, but the direction of this mass motion can only as yet be guessed at, and its rate is utterly unknown. The material for solving this, the great oceanographic problem, is rapidly accumulating, and when the physical and chemical reports of the *Challenger* Expedition have all been made public, it will be strange indeed if a large generalisation cannot be based upon them, and the discovery of the secret of ocean circulation be added to the many discoveries which have been made by the scientific men of the cruise.

The nature of this volume, both on account of the subjects with which it deals and the number of formulæ and long tables of numbers it contains, must have made the task of editing it no light one; and the accuracy of every part, the almost entire absence of typographical errors, and the beauty of the lithographed charts show that authors, editor, engravers, and printers have alike exerted themselves to produce a volume worthy of being the first to record the physical and chemical work of the *Challenger* Expedition. HUGH ROBERT MILL

SPECIALISATION IN SCIENTIFIC STUDY[1]

THERE once was a science called "natural philosophy," which, like some old synthetic types of animals, held in itself all the learning that applied to physical facts. By the beginning of this century this science of natural things had become divided into physics and natural history. These divisions have since spread,

[1] From *Science*.

like the divisions of a polyp community, until now natural history has more than a dozen named branches; and in physics the divisions are almost as numerous. There are now at least thirty named and bounded sciences; each name designating a particularly limited field, in which there are able men who work their days out in labour that does not consider the rest of nature as having any relation to their work.

This progressive division of labour follows a natural law: and it is perhaps fit that science should itself give a capital illustration of the application of this law to forms of thought, as well as to the more concrete things of the world; but it is an open question whether or no it is advantageous to the best interests of learning. There can be no question that the search for truth of a certain quality is very greatly helped by this principle of divided labour. If a man wish to get the most measurable yield out of the earth in any way, the best thing for him is to stake off a very small claim, tie himself down to it, fertilise it highly, till it incessantly, and forget that there are blossoms or fruit beyond his particular patch; for any moment of consciousness of such impracticable things as grow beyond his field is sure to find expression when he comes to dig his crop, whether his crop in the intellectual field be elements or animals, stars or animalculæ. The harvest of things unknown is most easily won in this kitchen-gardening way of work.

The world needs, or fancies that it needs, this kind of work; and it is now of a mind to pay more of its various rewards for the least bit of special and peculiar knowledge than for the widest command of varied learning. In a thousand ways it says to its students, not only as of old, "Study what you most affect," but, "*Effect that study altogether*, know the least thing that can be known as no one else knows it, and leave the universe to look after itself."

This is the prescription of our time. We are now proceeding on the unexpressed theory that, because no man can command the details of all science, therefore he shall know only that which he can know in the utmost detail. We seem to be assuming, that, if many separate men each know some bit of the knowable, man in general will in a way know it all; that when, in another hundred years of this specialisation, we have science divided into a thousand little hermit-cells, each tenanted by an intellectual recluse, we shall have completed our system of scientific culture. No one can be so blind to the true purposes of learning as to accept this condition of things as the ideal of scientific labour. It may be the order of conquest, the shape in which the battle against the unknown has to be fought; but beyond it must lie some broader disposition of scientific life,—some order in which the treasures of science, won by grim struggle in the wilderness of things unknown, may yield their profit to man.

The questions may fairly be asked, whether we have not already won enough knowledge from nature for us to return, in part, to the older and broader ideal of learning; whether we may not profitably turn away a part of the talent and genius which go to the work of discovery to the wider task of comprehension; whether we may not again set the life of a Humboldt along with the life of a Pasteur, as equally fit goals for the student of nature.

Until we set about the system of general culture in science, it will be nearly impossible to have any proper use of its resources in education. A sound theory of general culture in science must be preceded by a careful discussion of the mind-widening power of its several lines of thought. This determination cannot be made by men versed only in their own specialties; it must be made by many efforts to determine by comparison what part of the sciences have the most important power of mind-developing. At present there are few men whose opinion on such a subject is worth anything, and the number constantly grows less.

The greatest difficulty partly expresses itself in, and partly rises from, the multiplication of societies which include specialists as members, and specialties as the subjects of their discussions. We no longer have much life in the old academies, where men of diverse learning once sought to give and receive the most varied teaching. The geologists herd apart from the zoologists: and in zoology the entomologists have a kingdom to themselves; so have the ornithologists, the ichthyologists, and other students. "That is not my department," is an excuse for almost entire ignorance of any but one narrow field. If naturalists would recognise this "pigeon-holing," not only of their work, but of their interests, as an evil, we might hope to see a betterment. Until they come to see how much is denied them in this shutting-out of the broad view of nature, there is no hope of any change. Special societies will multiply; men of this sort of learning will understand their problems less and less well; until all science will be "*caviare* to the general," even when the general includes nearly all others beyond the dozen experts in the particular line of research.

The best remedy for this narrowing of the scientific motive would be for each man of science deliberately to devote himself, not to one, but to two ideals, *i.e.* thorough individual work in some one field, and sound comprehension of the work of his fellows in the wide domain of learning—not all learning, of course, for life and labour have limits, but of selected fields. In such a system there will be one society-life meant for the promotion of special research, and another meant for the broader and equally commendable work of general comprehension.

It is in a certain way unfortunate that investigation is to a great extent passing out of the hands of teachers. This, too, is a part of the subdivision work; but it is in its general effects the most unhappy part of it. As long as the investigator is a teacher, he is sure to be kept on a wider field than when he becomes a solitary special worker in one department.

The efforts now being made for the endowment of research will, if successful, lead to a still further tendency to limit the fields of scientific labour. A better project would be to keep that connection between inquiry and exposition from which science has had so much profit in bygone times.

TWO GREEK GEOMETERS

DR. ALLMAN in his article "On Greek Geometry from Thales to Euclid," in the current volume of *Hermathena* (vol. v. No. 10), discusses in Chapter IV. the discoveries of Archytas of Tarentum, and in Chapter V. those of the Greek geometer Eudoxus of Cnidus.

Archytas was a contemporary of Plato (428–347 B.C.), probably senior to him, and saved his life when Plato was in danger of being put to death by the younger Dionysius. These particulars and others of interest are skilfully arrayed by the author; one only of these we recall, viz. Horace's reference to the death of Archytas by shipwreck in an ode (Book I. 28), in which he recognises his eminence as an arithmetician, geometer, and astronomer. Unfortunately no undoubted works of his have come down to us; the authenticity of some that have been attributed to him is here discussed, but these do not treat of geometry. In former chapters his contributions to the doctrine of proportion and his demonstrations of theorems as well as solutions of problems have been noticed. Here the question of his identity with the Architas of Boethius' *Ars Geometriæ* is discussed, and a strong case made out for the same. The connection of Archytas with the Delian Problem (already touched upon in *Hermathena*, vol. iv.) next comes under consideration, and the passage in Eutocius is translated at length and accompanied by a figure. An enumeration of the theorems which occur in this passage is made,

whence we see that this geometer "was familiar with the generation of cylinders and cones, and had also clear ideas on the interpretation of surfaces; he had, moreover, a correct conception of geometrical loci and of their application to the determination of a point by means of their intersection." Dr. Allman further maintains that in this solution "the same conceptions are made use of, and the same course of reasoning is pursued, which, in the hands of his successor and contemporary Menœchmus, led to the discovery of the three conic sections. Such knowledge and inventive power surely outweigh in importance many special theorems." In arriving at these views he has to combat (which he does in some detail and apparently with success) the reasoning of Cantor, which is "based on a misconception of the passage in which the word τόπος occurs." Dr. Allman insists that τόπος means *place* and not *locus* (as used by mathematicians). The whole discussion is well worthy of the careful attention of all interested in the history of geometry: we must forbear to enter into the matter further.

Eudoxus (born about 407 B.C.), a pupil of Archytas, was an astronomer, geometer, physician, and lawgiver, and hence a noteworthy man in more ways than one. Here again Dr. Allman, one of whose great merits is his independence and his thorough examination of the original authorities, differs from Boeckh and Grote, but we cannot give details. A full discussion of the additions to geometry made by Eudoxus follows, and from it we learn how great he was as a geometer; his contributions to astronomy must be sought for elsewhere, though they too come under notice. "This eminent thinker—one of the most illustrious men of his age, an age so fruitful in great men, the precursor, too, of Archimedes and of Hipparchus—after having been highly estimated in antiquity, was for centuries unduly depreciated; and it is only within recent years that, owing to the labours of some conscientious and learned men, justice has been done to his memory, and his reputation restored to its original lustre." The article under notice will considerably conduce to this right placing of Eudoxus, amongst whose merits the least is not that he was a true man of science. "Of all the ancients, no one was more imbued with the true scientific and positive spirit than was Eudoxus." Five reasons for this statement follow, and the article closes. The whole paper is a most interesting as well as valuable one; indeed the interest grows as the author approaches his goal, and we venture to predict for Dr. Allman, when his articles appear in a volume, a most cordial welcome from all mathematicians.

THE ROYAL GARDENS AT KEW

THE Report of the Director on the Progress and Condition of the Royal Gardens at Kew for the year 1882 was unavoidably delayed. It bears date only from November 1, 1883, and was not published until well on in 1884. The date of the Report has, however, nothing to say to its interest and merit, and there is always plenty of both in these too short accounts of the great work carried on at Kew. Passing over some details, noting that the amount of damage which the collections have suffered has been, notwithstanding the unprecedented number of visitors, practically *nil*, and that the lecture-classes for young gardeners continue to give satisfactory results, we find an account of the formation of a Rock Garden at Kew. The site selected lies between the wall bounding the Herbaceous Ground on the east and the New Range on the west. The general idea in laying out this space was to imitate in some measure the rocky course of some Pyrenean stream; the dry bed is represented by the broad walk (8 feet wide and 514 feet long), while on either side are the rock-piled banks, in the interstices and pockets of which grow the Alpine plants, and above all are thickets of box and rhododendrons. Tree stumps have been somewhat freely used here and there. That some plants grow well on them will be admitted; that by their decay they require renewal is their chief drawback. The collection of 2630 plants bequeathed to the Gardens by Mr. Joad formed a splendid commencement to the Rock Garden series, and this section of the grounds has long since proved not only a centre of attraction to the general visitors, but has been a source of pleasure and profitable study to many an amateur gardener. An apology is made for not attempting some geographical arrangement of the Alpines; one was hardly needed. Where the plants grow best there ought to be their (artificial) habitat, and the practical gardener well knows what strange bedfellows plants often are, and how marvellously they vary in their tastes. Within the last six weeks we noted two finely-grown plants of that popular Alpine cudweed, the edelweiss; one was flowering out of a crack in a dry limestone wall, the other was on a deep clay bank.

The elaboration of the natural family of the palms for the "Genera Plantarum" of Bentham and Hooker led the Director to make a critical study of the species of palms in cultivation at Kew, the collection of which proved to be of unexpected richness. In an appendix is a classified list of 420 palms at present in cultivation at Kew. This collection has now but two rivals—the magnificent collection at Herrenhausen, Hanover, chiefly made by Herr Wendland, and that of the unrivalled tropical gardens at Buitenzorg in Java.

The report about the Arboretum shows an enormous amount of work accomplished. While the collection is one of the richest in existence, its importance is gradually more and more dawning upon those interested in planting, and its national importance in this respect should not be overlooked.

The part of the Report giving extracts from the large colonial correspondence that centres at Kew is full of interest, none the less so that much of the information is of a date often far on in 1883. The Argan tree seems likely to be acclimatised at Natal from seeds sent from Kew. The india-rubber (Ceara), introduced from Kew into Ceylon, seems in a fair way of paying as well as Cinchona. Dr. Trimen says it will grow anywhere up to almost 2500 feet, and its commercial success is most satisfactory. "About six months ago (October 24, 1883) some Ceara-rubber seed was imported from Ceylon into Southern India. The produce of these trees may now be seen flourishing in a wonderful manner at the foot of the Neilgherry Hills. The rapid growth of the trees is marvellous. Some which were six months old from seed were fully eight feet high; and a cutting, said to have been planted scarcely six months previously, was quite eight feet high, and was in blossom. It seems to thrive on poor soil, requires shelter but not shade, and very little rain. The demand for the produce seems to be unlimited." Of the mahogany seeds sent from Kew in 1863 to Mauritius, nine of the trees raised bore seeds in 1881, and numerous seedlings were found self-sown. In a report from the Seychelles allusion is made to "three different diseases which have seriously affected the cocoa-nut palms," whereby large forests of these valuable trees have been destroyed. No details are given as to what these diseases are, though they "have nearly stopped their depredations since 1882." In the same report it is mentioned that the remains of the clove plantations cover "about 250 acres"—surely a mistake. It is also stated that the Liberian coffee sent from Kew in 1880 has proved a success, and that about 100 acres of it have been recently planted. The report on *Cinchona robusta* quotes with approval Dr. Trimen's views on the hybrid forms of the Nilgiris—known under the names *pubescens* and *magnifolia*—now settled to be hybrids between *C. succirubra* and *C. officinalis*.

Among the more important additions to the Herbarium may be mentioned the collection of European and exotic lichens made by the Rev. W. A. Leighton, the type speci-

mens of Mr. Wilson Saunders's Refugium Botanicum, the Madagascar collection of the Rev. R. Baron—this latter of over 1100 species.

Reference is also made to the "North Gallery," an illustration of which is added to the Report. The collection of separate pictures of plants in the gallery amounts in number to 627, and has since been added to.

It will be seen from this brief sketch of Sir Joseph Hooker's Report that the work done at Kew is as varied as it is important, and that our colonies directly and our mother country indirectly are under lasting obligations to the zeal and energy of all concerned in the management of this great institution.

MR. THORODDSEN'S GEOLOGICAL EXPLORATIONS

ALTHOUGH situated at a comparatively short distance from Europe, and notwithstanding the frequent visits of late years by English tourists, Iceland is yet very far from being a well-known country. The upland is still, for the most part, an unexplored region, and there are whole districts where no man, native or foreign, ever set his foot, owing, chiefly, to the difficulties and dangers which attend travelling through these wildernesses. Foreigners travel mostly along beaten tracks; they come mostly without having acquired any previous knowledge of the peculiar nature of the country, consequently not knowing what parts are most worth visiting or exploring. Yet these regions are eminently interesting for students of natural science, being filled with innumerable glaciers, some of enormous magnitude, with multitudes of volcanoes, eruptive springs, &c., which it is of the greatest importance should be scientifically explored and described. In order to obtain reliable information about these upland wilds of the country, the Government of Iceland have commissioned Mr. Th. Thoroddsen to undertake systematic explorations with a view to establishing the geology of the country on a sound basis, and correcting its geography where necessary; for this purpose he has already undertaken various expeditions. In the course of last summer (1883) he explored the peninsula of Reykjanes and its upland connections. Although this part lies in close proximity to the inhabited parts of the country, it has hitherto remained for the most part a *terra incognita* on account of the innumerable waterless and utterly barren lavas which are crowded into it, and make travelling excessively arduous. Formerly people only knew that within historic times two volcanoes had been active in these parts. Mr. Thoroddsen has now determined the existence and site of no less than *thirty* separate volcanoes with at least *seven hundred* craters. In each case he has made all necessary measurements, and has constructed a geological map of the whole district.[1] The aggregate extent of the lavas covers about 44 square (geographical) miles. Out of the lavas up and down this tract there rise mountains composed of tufa and breccia, and through these the eruptions of the volcanoes proper have found their vent. Cases of individual volcanoes being built up in one spot by repeated eruptions are rare. The craters are in most cases traceable in distinct long rows, like pearls on a string, along terraces of tufa, situated along chasms through which the lava welled out. In some places there are no craters, the lava having boiled out of the chasm over either side of it, in which cases the rift remains open with its brims covered with a glazed crust of lava. In other localities are found volcanoes of colossal size, broad sublevations or convexities of lava, with a large crater at the apex from 800 to 1000 feet in diameter, instances of which are Skjaldbreid, 3400 feet, and Heidin-Há, 2000 feet above the level of the sea. Throughout the lava stretches one comes upon enormous fissures all following the same direction as the rows of the craters, namely, south-west to north-east. All about this district there are also found numbers of hot springs, solfataras, and boiling clay-pits. This peninsula, Mr. Thoroddsen maintains, must be one of the most thoroughly burnt spots on the globe, and a pre eminently instructive tract for geologists who make volcanic manifestations the speciality of their study.

[1] published by the Geological Association of Stockholm.

This summer Mr. Thoroddsen is engaged in exploring the enormous lava wilderness of Odádahraun, covering the central part of Iceland, and, as yet, for the most part entirely unknown. In the glaciers to the south of this wilderness great eruptions have taken place of late years, about which nothing is known, no one having as yet ventured into these wilds, lying 3000 to 4000 feet above the level of the sea. The difficulties of exploration here are enormously aggravated by the utter barrenness of the region, by scarcity of water, and by the frequent snow tempests by which the region is constantly harried even in the midst of summer. Even the compass is not to be relied upon, on account of the mass of iron which enters to such a large extent into the composition of the lava.

Akreyri, June 24, 1884

Grimsey is the name of a small island, situated in the Arctic Ocean, about 22 English miles due north of the promontory which divides the bays of Eyjafjord and Skagafjord in Northern Iceland. It is inhabited by 88 human beings, debarred from all communication with the outer world, and equally ignorant of its motive thought as of its stirring events. Their intercourse with outward surroundings is confined to Arctic ice and ceaselessly recurring storms. Only once or twice a year they manage in their small open boats, at a perilous risk, to effect a landing on the mainland, for the purpose of obtaining by barter their necessaries of life at some of the north coast trading stations.

The island having never before been visited by a naturalist, I eagerly embraced the opportunity of joining the governor of the North District on an expedition to it, undertaken at the instance of the commander of the gunboat *Diana*, Capt. O. Irminger, of the Danish navy. In the evening of June 19 we steamed, in calm weather, from Akreyri down the broad bay of Eyjafjord, enjoying the imposing scenery of the mountains on either side, lit up by the subdued vermilion tints of the nocturnal sun glare; when we reached the mouth of the bay, we had a full, unintercepted view of the midnight sun, resting on the oceanic sky-line, like a ball of fire behind a veil of blood. Out of the inert calm of the deep, which looked like polished glass, there rose on either side of us black precipitous rocks that formed, as it were, the advanced basis of the snow-capped mountain-tops, which determined our sky-line in the landward distance.

We reached Grimsey at three o'clock in the morning of the 20th, still, as good luck would have it, favoured by the same calm weather and quiet sea—both being the indispensable condition of effecting a safe landing on the island. We took the shore just below the parsonage in a bight formed of precipitous rocks made of basaltic columns, here and there split up by yawning caves; and having succeeded in clambering to the top of the rocks, we set about exploring the island.

The formation of Grimsey is basaltic throughout, and, geologically speaking, resembles, closely on the whole, the stratification of Northern Iceland. From its non-volcanic nature one may therefore fairly assume that, once upon a time, it must have been connected with the mainland. But, though not volcanic itself, it seems that Grimsey is not very far removed from the lines along which the active subterranean fires in Iceland are operating. At various times the inhabitants state they have observed towards the south-east signs of submarine volcanic action, and towards Tjörnes (S.S.E.) a column of fire was distinctly observed breaking through

the surface of the sea in 1868; this, too (one of the northernmost promontories of Iceland), has frequently been visited by violent earthquakes, notably so in 1872. Towards the east the island rises precipitously out of the sea to the height of upwards of 300 feet, but slopes to the westward, where all the habitations of the people are scattered about. The flora is scanty, and the plants stunted in a remarkable degree; as far as I had opportunity to observe, the vegetation seemed to bear a distinct Arctic impress as compared with that of the mainland. The sward is covered with Arctic willow (*Salix herbacea*), resembling the same plant when met with on the mainland at an elevation of 1500 to 2000 feet above the sea-level. The flora of the eastern portion of the island is much more varied, as compared with that of the western, owing to the soil being much more fertile there from the guano deposited by the multitudes of birds which haunt that part of the island. Every ledge of rock is covered with the so-called "Skarfa-kál" (scurvy-kale, scurvy-grass, or spoon-wort, *Cochlearia officinalis*). Altogether I managed to collect here between fifty and sixty species of plants, all of which are also found on the mainland, only these are of a more stunted growth. No heath vegetation occurred, and no ligneous, if I except the above mentioned willow, which only grows to the height of one inch and a half.

The temperature of Grimsey is much milder than might be supposed from the geographical position of the island. Although it is visited every two out of three years by the Arctic ice, the average temperature of the year is $+1^\circ{\cdot}4$ Celsius. August is the hottest month in the year, $+7\frac{1}{2}^\circ$ C.; March the coldest, $-3\frac{1}{2}^\circ$ C. The highest degree of heat in 1876 was $+20^\circ$ C.; the greatest cold in 1880, -30° C. The mildness of the temperature is accounted for by the fact, ascertained of late years beyond a doubt, that a small branch of the Gulf Stream splits off from the main current on encountering the resistance of the western submarine spurs of the rocky masses on which Iceland is built up, the flow of which branch, on wheeling round the north-western peninsula of the country, takes an eastward direction along the whole extent of the northern coast. The average temperature of the sea round Grimsey is about 4° C. in January and 3° C. in February. The pastor of the island, M. Pjetur Gudmundsson, has for many years been engaged in exceedingly careful meteorological observations on behalf of the Meteorological Institute of Copenhagen. This most worthy gentleman, living here in conspicuous poverty, like a hermit divorced from the world, though he has the comfort of a good wife to be thankful for, is not only regarded as a father by his primitive congregation, but enjoys moreover the reputation of being in the front rank among sacred poets in modern Iceland.

The inhabitants derive their livelihood, for the most part, from bird-catching, nest-robbing, and deep-sea fisheries. The precipices that form the eastern face of the island are crowded with myriads of various kinds of sea-fowl. On every ledge the birds are seen thickly packed together; the rocks are white with guano, or green-tufted with scurvy-grass; here everything is in ceaseless movement, stir, and flutter, accompanied by a myriad-voiced concert from screamers on the wing, from chatterers on domestic affairs in the rock-ledges, and from brawlers at the parliament of love out at sea, the surface of which beneath the rocks is literally thatched at this time of the year with the wooing multitudes of this happy commonwealth. If the peace is broken by a stone rolled over the precipice, or by the report of a gun-shot, the air is suddenly darkened by the rising clouds of the disturbed birds, which, viewed from the rocks, resemble what might be taken for gigantic swarms of bees or midges.

The method adopted for collecting eggs is the following:—Provided with a strong rope, some nine or ten stalwart men go to the precipice, where it is some 300 feet high, and one of the number volunteers or is singled out by the rest for the perilous "*sig*," *i.e.* "sink," or "drop," over the edge of the rocks. Round his thighs and waist, thickly padded generally with bags stuffed with feathers or hay, the "*sigamadr*," "sinkman," or "dropman," adjusts the rope in such a manner as to hang, when dropped, in a sitting posture. He is also dressed in a wide smock or sack of coarse calico, open at the breast, and tied round the waist with a belt, into the ample folds of which he slips the eggs he gathers, the capacity of the smock affording accommodation to from 100 to 150 eggs at a time. In one hand the "sinkman" holds a pole, 16 feet long, with a ladle tied to one end, and by this means scoops the eggs out of nests which are beyond the reach of his own hands. When the purpose of this "breath-fetching" "sink" is accomplished, on a given sign the "drop-man" is hauled up again by his comrades. This, as may readily be imagined, is a most dangerous undertaking, and many a life has been lost over it in Grimsey from accidents occurring to the rope.[1]

For the pursuit of the fishery the island possesses fourteen small open boats, in which the men will venture out as far as four to six miles cod-fishing; but this is a most hazardous industry, owing both to the sudden manner in which the sea will rise, sometimes even a long time in advance of travelling storms, and to the difficulty of effecting a landing on a harbourless island.

Now and then the monotony of the life of the inhabitants is broken by visits from foreigners, mostly Icelandic shark-fishers, or English or French fishermen.

Of domestic animals the islanders now possess only a few sheep. Formerly there were five cows in the island, but the hard winter of 1860 necessitated their extermination, and since that time, for twenty-four years, the people have had to do without a cow! Of horses there are only two at present in the island! Strange to say, the health of the people seems, on the whole, to bear a fair comparison with more favoured localities. Scurvy, which formerly was very prevalent, has now almost disappeared, as has also a disease peculiar to children, which, in the form of spasm, or convulsive fit, used to be very fatal to infant life in former years.

Inexpressibly solitary must be the life of these people in winter, shut out from all communication with the outer world, and having in view, as far as the eye can reach, nothing but Arctic ice. The existence of generation after generation here seems to be spent in one continuous and unavailing Arctic expedition. The only diversion afforded by nature consists in the shifting colours of the flickering aurora borealis, in the twinkling of the stars in the heavens, and the fantastic forms of wandering icebergs. No wonder that such surroundings should serve to produce a quiet, serious, devout, and down-hearted race, in which respect the Grimsey men may perhaps be said to constitute a typical group among their compatriots. However, to dispel the heavy tedium of the long winter days, they seek their amusements in the reading of the Sagas, in chess-playing, and in such mild dissipations at mutual entertainments at Christmas-time as their splendid poverty will allow.

TH. THORODDSEN

SEATS IN RAILWAY CARRIAGES

In a recent article in *Science et Nature* the writer, after animadverting on the lateness of the day at which shoemakers have at length begun, though still very imperfectly, to take account of the osseous framework of the human foot, proceeds to investigate the relation between

[1] This is a fate that befalls too many of the "sinkmen" of Iceland, for there are numbers of them all round the coast. It would be easy, at a very small cost to the treasury of Iceland, to provide a perfectly safe movable apparatus for every district where life must be sustained at the above-described risk. The authorities would, no doubt, readily meet any reasonable request on the subject.—E. M.

the structure of the human trunk and that of the seat, more particularly in railway carriages, designed for its accommodation. In a sitting posture the pelvis has for its sole function the support of the upper part of the

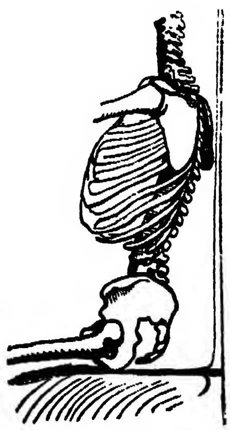

FIG. 1.

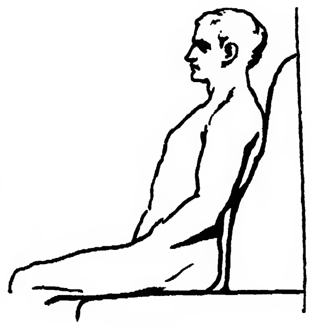

FIG. 2.

body. The spinal column, however, is inserted in the pelvis, not in the form of a straight line but of a curve (Fig. 1). This inflection on the part of the backbone, while adding to the mobility of the trunk, imposes on it

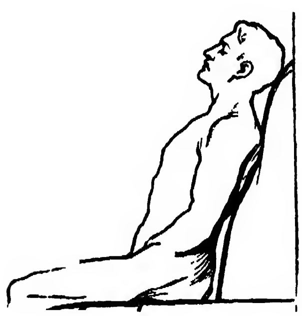

FIG. 3.

FIG. 4.

the necessity of a continual balancing movement, the centre of gravity being shifted every time the head and thorax sway to one side or the other. Such balancing

FIG. 5.

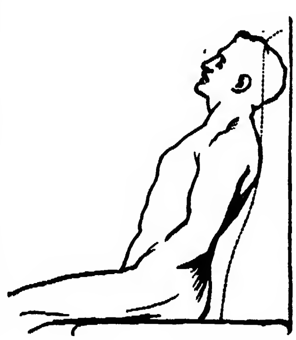

FIG. 6.

movement is necessarily also attended by a certain expenditure of energy. To allow the upper part of the body to remain comfortably at rest there must be supports for the back, the shoulders, and the head. So far as these are wanting, the body will tend of itself, unless counteracted by an effort of will and nervous force, to bend forward, till at last the forehead finds the knees to lean on. The position of the body in sitting is all the easier, and its rest all the more complete, the more decided is the inclination of the back of the seat and the more obtuse is the angle formed by the trunk and

the thighs. Seats such as the *dormeuses* realise the most favourable conditions in this respect.

Fig. 2 represents a man comfortably seated and propped. The back of the seat supports him principally under the shoulder-blades, offers the chest a depression to sink in, and altogether keeps the upper part of the body in a free and easy position. Fig. 3 shows the same person in a similar position, but with his head resting

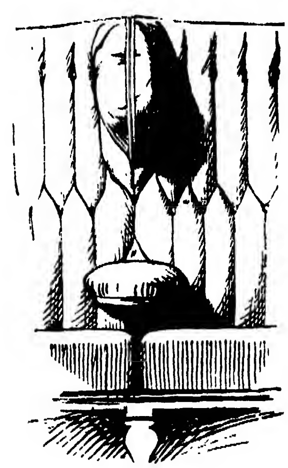

FIG. 8.

behind. In both these figures the back of the seat is seen exactly in profile, and to the writer of the article such seems the construction which is most convenient in railway carriages.

Fig. 4, on the other hand, represents the profile of a man seated as passengers are in many of our actual first-class carriages. His position is perceived to be a forced one in contrast with that just noticed, and alto-

gether disagreeable. Fig. 5 shows exactly the stiff attitude the head is compelled to take in order to rest.

Finally, Fig. 6 reproduces the comfortable position indicated in Fig. 3, and at the same time represents the profile of the back of the seat actually in use in our railway carriages. On comparing this profile with the position of the man comfortably supported, the following defects in the back of the seat are observed:—

1. It is too vertical.

2. It allows an empty space between the lumbar vertebræ and the lower extremity of the shoulder-blade exactly at the place where one is in the habit of putting a cushion "behind the back," as it is called.

3. It is at least half a foot too high, and so makes it impossible for the head to rest behind. It is customary to make the back of the seat tally with the height of a man of average size seated bolt upright.

Under the actual conditions, such as they have been

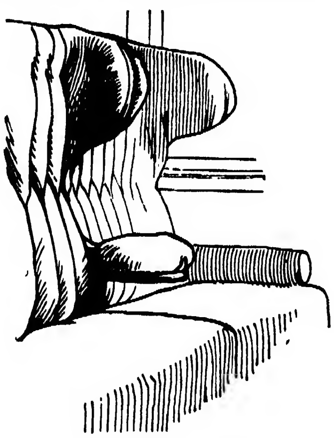

FIG. 9.

described, what becomes of the traveller when sleep at length overtakes him? Little by little he slides down on his seat till the lower extremity of his shoulder-blades, which has most need of support, finds the most sensible projection, which, as the backs of our railway carriages actually are, is precisely where it is least serviceable—at a point, namely, on a level with the region of the pelvis. Lastly, the head inclines forward or to the side, if it does not bury itself in the breast (Fig. 7).

Fig. 8 gives a front view of the face of the bench serving as the back of the seat. In the centre is seen a stuffed projection, on each side of which a passenger may rest his cheek. The shoulder, getting no separate support, must contrive to lodge itself between this stuffed projection and a kind of plateau fixed in the side of the back of the seat, and which, situated about a hand's breadth above the seat, offers a resting-place to the elbow (Figs. 8 and 9).

A NEW PRINCIPLE OF MEASURING HEAT

THE following method is intended to fulfil some conditions which probably will be more and more urgently required in the progress of modern science:—

I. *Measurements of heat should be executed at constant temperature, i.e. without the aid of thermometers.*—Every variation of temperature during calorimetric experiments causes unavoidable errors and necessitates corrections and compensations. The accuracy of the thermometric method ["method of mixture," of Regnault], which now predominates among experimentalists is unrivalled, only in those cases where the amount of heat to be measured is developed in the course of a few seconds or minutes; it is seriously impaired whenever the experiment lasts longer, while the influence of the corrections for radiation, &c., increases proportionately with the duration of the operation. The first method used in thermo-chemical investigations, the ice-melting method of Lavoisier and Laplace, as well as the modern calorimetric method by Bunsen, avoids this inconvenience by executing all measurements at the melting-point of ice. Bunsen's ice calorimeter is, however, not exempt from corrections. Every physicist familiar with the use of this instrument will also, like the author, be well acquainted with its capriciousness. Bunsen prescribes that the calorimeter should be placed in a large vessel filled with absolutely pure snow. Although I have had abundant quantities of the purest snow at my disposal, I do not hesitate to declare, having tried, in company with Prof. Nilson, a whole winter to obtain reliable results with the original arrangement of the inventor, that the instrument would be impracticable for use without the improvement devised by Schuller and Wartha, viz. to immerse the calorimeter in a vessel containing ice and pure water at 0° C. Still the advantage of this arrangement is not to prevent variations in the position of the mercury index, but to make them quite *regular*. These variations are declared by some physicists to depend upon the vacillation of atmospheric pressure, but I think that the real

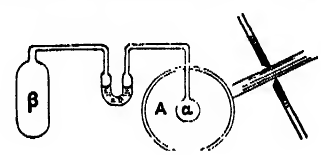

FIG. 1

cause of the unsteadiness of the index of the instrument lies in the peculiar behaviour of the ice in the vicinity of its melting-point. It was believed hitherto (and Bunsen's method theoretically rests upon this assumption) that ice at 0° C. suddenly changes its specific volume from that of ice [= 1·090686][1] to that of water [= 1·000000]. I admit that this assumption *may* be true with regard to *absolutely pure ice*, but in every kind of frozen water which contains the smallest trace of impurity (which is unavoidable if the water has been boiled assiduously in a glass vessel) the transition of ice into liquid water is not sudden, but gradual, *and begins already a little below 0° C.* Such ice does not attain its maximum of volume exactly at 0° C., but some hundredths or tenths of a Centigrade degree below 0° (dependent upon its relative purity). Graphic representation[2] shows that the co-ordinate of specific volume of the ice comes not to a *point d'arrêt* at zero, but moves upon the rapidly-sloping branch of a curve just in the immediate vicinity of the melting-point. Now suppose the water in the external vessel to be either a little purer than that of the calorimeter, or *vice versâ*. In the

[1] This number, which is almost identical with that of Bunsen, was found by the author in his research "Upon the Properties of Water and Ice," "*Vega*-expeditionens vet. iakttagels," Bd. ii. p. 275.

[2] See the paper "Upon Water and Ice," by O. Pettersson, *l.c.*

former case its temperature, *i.e.* its melting-point, will be situated a few thousandths of a Centigrade higher, and the volume of the ice in the calorimeter will move down-

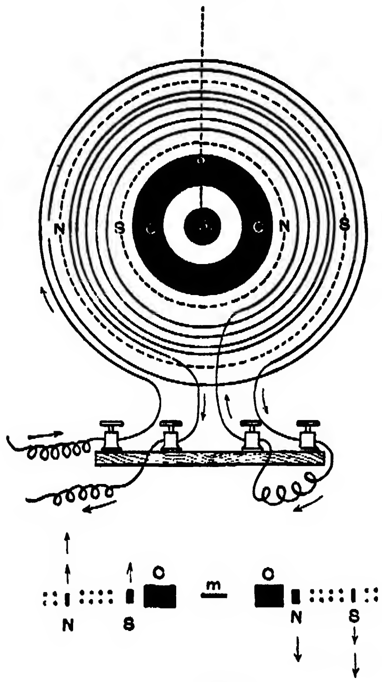

Fig. 2

wards on the branch of the curve in the attempt to gain the temperature of the surrounding medium. Then the index will move slowly backwards; in the other case the co-ordinate of specific volume will move upwards on the

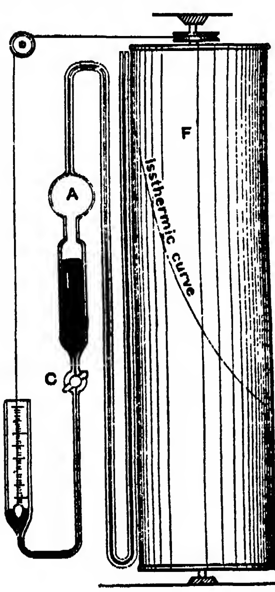

Fig. 3

sloping branch, and the index of the scale-tube will march forwards. These remarks may be sufficient to explain why there has been much dispute about the absolute magnitude of the caloric units indicated by the ice calorimeter of Bunsen, and why this instrument is always *empirically* graduated, although its principle ought to allow *of absolute* measurements.

II. *The amount of heat developed in calorimetric experiments should be directly transformed into work and measured in absolute units* [kilogramme-metres].[1]—In every branch of physical science this manner of measurement is beginning to introduce itself, as, for example, in electricity, magnetism, &c. In thermal determinations it has the great advantage that the mechanic units are 430 times greater than the thermic units, and can be far more accurately determined.

III. *The principle should be applicable to the measurement of all kinds of caloric energy: as, specific heat, radiant heat, the heat absorbed or developed by chemical reactions, &c.*—It must be remarked that I have hitherto experimented only with *radiant heat.* An apparatus intended for other kinds of heat is under construction,

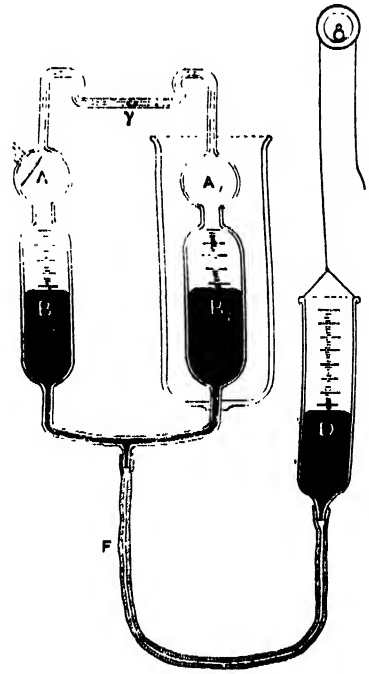

Fig. 4

but as this will take some time, and as I wish specially to direct my labour to the determination of the sun's radiant heat, I take the opportunity now of calling the attention of physicists to the principle of the method, which I foresee can be developed and varied in a multitude of ways. In case the matter should interest anybody sufficiently to make him try it experimentally, I will give some information in order that he may not be detained by those difficulties which have baffled my own efforts during nearly six years. The principle is extremely simple, and will be easily understood by a glance at the diagram (Fig. 1).

Let a beam of heat rays fall upon the thin glass wall of the reservoir A, which contains dry air. As soon as the thermometer $\alpha\beta$ indicates that the temperature of the air in A *increases*, let mercury escape through the stopcock C. Thereby the air *expands*, and the heat received by radiation is transformed into mechanic work, as the level of mercury in B sinks under the influence of the expanding force imparted to the air by the radiant heat.

[1] I denote this in the following by the sign M:K°.

As the air in A in this case has expanded *isothermically*, the mechanic work is represented by the equation

$$x = p_0 v_0 \log_{\text{nat}} \frac{v}{v_0},$$

where $p_0\ v_0$ are the initial pressure and volume of the air in A, and v is its volume after the expansion. If we suppose that a beam of sun rays during a minute has fallen upon the blackened surface of A through a hole of a square centimetre, and that the experimenter has neutralised the tendency of the air to increase in temperature by careful manipulation of the stopcock C, which allows the air to expand its volume as it displaces the escaping mercury—suppose that in this way the cooling effect of the expansion has neutralised the tendency of the air to augment its temperature under the influence of the heat radiation, so that the index of the thermometer has been kept *constantly* at its initial point, then the *entire* amount of solar heat imparted to the glass reservoir A is converted into mechanic work by means of the isothermic dilatation of the air, and the value of x found by the above equation represents what is called by modern scientists "the solar constant."[1]

It is obvious that the chief difficulty lies with the thermometer. The indications of this part of the instrument must be *extremely sensitive* (up to some thousandths of a degree Centigrade) and *instantaneous*, in order that the experimenter may be able to regulate the expansion so that a real isothermic dilatation takes place. I judged that only two kinds of thermometers could suit the purpose, and tried first a differential glass thermometer. This is in fact very sensitive, but as the pressure in A diminishes during the experiment, the bulb *a* expands somewhat, and this has a disturbing influence upon the index. I next inserted in A a network of very thin thermo-electric elements (combinations of iron and German silver), and observed the alterations of temperature of the air in A by means of a mirror galvanometer. As I found the ordinary system of magnets in galvanometers far too heavy for the instantaneous deflections here required, I constructed a new kind of galvanometer, whereof I give a schematic view in Fig. 2, because I think that it may really do some good work in other cases, as it proved to be extremely sensitive. The dotted lines represent a system of two concentric (annular) magnets made of steel springs (from watches), each magnetised to saturation between the poles of a powerful Plücker electro-magnet. They are combined in the astatic manner, but the dimensions of the material are chosen so that the *inner* magnet has just sufficient force to keep the whole system in the magnetic meridian. The figure shows the position of the insulated copper wires relatively to the magnets. M is a mirror of very thin silvered glass; C C is a massive copper ring. I tested the sensibility of the instrument by adiabatic expansion of the air in A. This was effected by opening the stopcock C for a moment. The slightest dilatation of the air in this manner immediately showed its cooling effect by a deflection of the scale in the mirror, but as the deflection soon brought the magnets out of the electric field, the *amplitude* of the oscillation was, as I had calculated, not great. However, as the oscillations did not cease instantaneously, I found the method impracticable for *continuous* observation. I then abandoned the project of regulating the isothermic expansion *by means of a thermometer* altogether.[2]

The next arrangement, which succeeded better, was that shown in Fig. 3. Here the co-ordinates of the isothermic curve are traced out beforehand on the rotating cylinder F. As the mercury in B flows into D, it lifts a float, which, by a combination of wire and blocks, makes the cylinder rotate at a rate which is proportional to the expansion of the volume of the air in A. Thus the horizontal co-ordinate (v) of the isothermic curve is represented. The vertical co-ordinate of the pressure of the air in A (p) is represented by the height of the liquid in the open branch of the manometer. The operator only has the task to regulate the outflow of the mercury from B to D by means of the stopcock C, so that the level of the fluid in the manometer closely follows the isothermic line drawn upon the paper envelope of the rotating cylinder. This is not difficult after a little experimenting. Whenever the level in the manometer shows a tendency to rise above the isothermic line, there is a surplus of heat in A waiting for transformation into work, which can be effected by accelerating the outflow of the mercury through C. The area contained between the initial and final ordinates [p_0 and p, represented by the positions of the column of liquid in the manometer-tube relatively to the cylinder at the commencement and the close of the experiment] represents the value of the integral—

$$p_0 v_0 \int_{v_0}^{v} \frac{dv}{v}$$

or *the amount of mechanic work equivalent to the transformed caloric energy*. Thereby this method affords an elegant manner of showing the actual transformation of all kinds of heat into work to an auditory. In order to obtain indications on a grand scale I always used H_2SO_4 tinted blue with indigo in the manometer. The rotating cylinder is about 2 m. high, and a quantity of heat of not more than 8·76 gramme-calories, imparted by radiation or otherwise to the air in A, makes the cylinder rotate 360°, and the level of the liquid in the manometer sink 1·84 m.[1] The volume of A was 400 c.c., and the initial pressure equal to 1000 mm. (of mercury). But for scientific measurements I cannot recommend this method. The sulphuric acid *adheres* to the glass tube, and does not take up its definitive level *at once*, the dimensions of the apparatus become inconveniently large, the co-ordinate p cannot be traced out on the paper of the cylinder directly from the isothermic equation,

$$p v = R T_0,$$

but must be recalculated with the aid of some corrections arising from the influence of the atmospheric pressure upon the columns of liquid in the manometer and in D, too complicated to be mentioned here.

Fig. 4 shows a kind of calorimeter which realises the condition of isothermic dilatation of the air in the most simple manner and still is capable of the most accurate measurements.

A and A_1 are very thin glass vessels fabricated of equal shape and size by Franz Müller in Bonn. Both contain dry air over mercury, which stands at equal height in B and B_1. If the graduated glass tube D, which communicates with A and A_2 through a caoutchouc tube, is raised or lowered by means of the arrangement shown in the figure, the level of the mercury rises or sinks equally in B and B_1, and the air in A and A_1 is compressed or dilated equally, provided that the temperature is kept *constant* in both. This condition is realised in A_1 by the surrounding *large* mass of water, which imparts to the air and mercury in A_1 and B_1 its own constant temperature. *The air in* A_1 *therefore always expands or contracts isothermically.* If its initial volume and pressure are denoted by v_0 and p_0, the law of Mariotte,

$$v p = v_0 p_0,$$

will always regulate the expansion of the air in A_1. It is easy to see that this will also be the case in A, if the experi-

[1] Uncorrected.

[2] I think the thing will be very difficult to realise in this way. If another indicator could be substituted for the galvanometer, for example, the Lippmann capillary electrometer in the ingenious form devised by Chr. Lovén, the experiment would be very easy. But, unhappily, this instrument is insensible to thermo-electric currents.

[1] *i.e.* theoretically. This height is somewhat reduced by the correction of the pressure, &c.

ment is conducted so that during the dilatation of the air in A and A_1 the index of the differential thermometer γ, which combines both instruments, is kept *constant*. Suppose then a beam of heat rays to fall upon a thin piece of platinum foil[1] in A *through the glass wall*. The immediate effect of radiation is to elevate the temperature of the air in A, but as an increase of only 0·0016 of a centigrade causes a displacement of the differential index γ of 1 mm.,[2] it is easy for the operator to compensate this tendency and transform the heat into work by lowering the graduated tube D, which makes the air in A and A_1 expand. This expansion is *isothermic* in both, because volume and pressure varies in the same way in A as in A_1, where it, as shown formerly, follows Mariotte's law.[3] The rate of expansion of the air is indicated by the rise of the mercury in the calibrated tube D. The sensibility of the differential index is so great that it requires a very steady hand to regulate the movement of D so that the index keeps constantly at its initial point, without making greater excursions to either side than 1 or 2 mm. Every irregularity in the movement changes the isothermic expansion into adiabatic dilatation or compression. I therefore prefer to regulate the sinking of D by means of a screw. During the experiment A must be protected by isolating screens, &c., from outward disturbing thermal influences. I think I have realised this in a satisfactory way, but as a detailed account of the arrangement would be too long, I must reserve the complete description for a future paper.

Lastly I will mention some examples of determinations of the radiant heat emitted by a regulation gas-burner at 22·5 cm. distance from A. The radiation was admitted through a screen with an opening of $4\frac{1}{2} \times 2\frac{1}{2}$ cm. The initial volume of the air in A[4] was 622·22 c.c. The pressure was brought to 760 mm. Experiment I. was made at noon, II. in the afternoon of the same day.

Experiment I.—Increase of volume by expansion during 6 minutes = 185·9 c.c. Mechanical equivalent of the radiation during 6 minutes = 1·680 M.K°. Mechanical equivalent of the radiation during 1 minute = 0·280 M.K°.

Experiment II.—Increase of volume, &c., during 5 minutes = 158·5 c.c. Mechanical effect of radiation in 5 minutes = 1·459 M.K°. Mechanical effect of radiation in 1 minute = 0·291 M.K°.

I have measured in this way the mechanical effect of radiations, the caloric energy of which was only 0·08 of a gramme-calorie in the minute. *This method is free from every kind of correction*. It is obvious that, by means of a thin test-tube hermetically inserted into A, calorimetric determinations of specific heat, &c., could be made, but I have not yet arranged the apparatus for this purpose.

OTTO PETTERSSON

Stockholms Högskolas Laboratorium, June 25

NOTES

THE Government have directed Dr. Klein, F.R.S., and Dr. Heneage Gibbes, to proceed to India to pursue a scientific inquiry into the nature of cholera. It is understood that these gentlemen will act in conjunction with the Commission nominated a few weeks ago by the Indian Government for the same object.

AT the meeting of the Council of the Marine Biological Association on Friday, July 25, Prof. Moseley in the chair, the names of Prof. Allman, F.R.S., and Sir John St. Aubyn, Bart., M.P., were added to the list of Vice-Presidents, and Mr. Spence Bate of Plymouth was elected on the Council. It was decided that, provided certain arrangements promised by a committee of the Town Council of Plymouth were carried out, the Association should proceed to erect its first laboratory on Plymouth Sound. Plymouth is not only the best position for the laboratory on account of its natural features, but the local committee has offered to the Association a free site on the seashore and a subscription of 1000*l*. A vote of thanks to H.R.H. the Prince of Wales for having become the Patron of the Association was carried. The financial prospects of the Association were reported as highly satisfactory. The building of the laboratory will probably be commenced in the spring.

THE eighth International Medical Congress is to be held in Copenhagen from August 10 to 16. President, Prof. Dr. P. L. Panum; Secretary, Dr. C. Lange, both of Copenhagen. Among the most eminent of the 658 medical men who have engaged to attend are:—Prof. Lister, Sir William Gull, Bart., Prof. Dr. L. Pasteur, Prof. Paul Bert, and Prof. Dr. R. Virchow.

THE Congress of the British Medical Association opened in Belfast on Tuesday. Prof. Canning directed his presidential address mainly to an analysis of the origin and causes of the spread of epidemic diseases.

THE prospectus has just been issued of the new "Società di Geografia ed Etnografia," founded in Turin in anticipation of the Italian Geographical Congress, which meets in that city on August 15. The Congress is a passing event, but the Society has probably a brilliant career before it, established as it is under the auspices of Prof. Guido Cora, its first President. The well-known *Cosmos* of the distinguished geographer becomes the authorised scientific *Journal* of the Society, a happy arrangement which cannot but prove mutually beneficial. In other respects everything is for the present provisional, and the council, including besides Sig. Cora such names as those of Luigi, Schiaparelli, Enrico Morselli, and Alessandro di Cesnola, holds office only till the beginning of next year, when the statutes will be definitely settled, and a permanent administration established. Meantime it is satisfactory to find that ethnology, a branch of geographical science so strangely neglected by existing geographical institutes, is to receive all due prominence and encouragement. Another important feature is the attention to be paid to commercial and industrial geography, especially as regards Italy in its relations with foreign countries. This idea also, *mutatis mutandis*, might be advantageously adopted by similar learned bodies elsewhere.

THE *Bollettino* of the Italian Geographical Society for July publishes the circular, regulations, and programme of the first Italian Geographical Congress, which meets in Turin from the 15th to the 19th of next August under the presidency of the President of the Italian Geographical Society. All except honorary members to be specially named will be expected to contribute towards the expenses sums varying from ten to thirty francs. In return they will have free access to all the scientific gatherings, and will be entitled to a copy of the *Proceedings* of the Congress. There will be two Sections—a Scientific and Commercial, and questions will be discussed in connection with mathematical, physical, ethnographic, political, economic, and historic geography. Amongst the subjects proposed for discussion are the following:—"What ethnological conclusions are to be drawn from the more recent anthropological and philological data, regarding the indigenous populations of East Africa?" "Considering the part already taken by Italy in scientific exploration in the Polar seas, what are the best means of organising an independent Italian expedition to the Antarctic regions?" "On the need of preparatory schools for training

[1] It is blackened in the following way. It is galvanically coated with a thin layer of metallic copper, and afterwards heated in a current of oxygen. This arrangement gives most sensitive indications.

[2] This is the case in the apparatus constructed by the author. The index there consists of a small drop of coloured alcohol. If H_2SO_4 is substituted for the alcohol, the sensibility of the apparatus is lessened considerably.

[3] In my last constructed apparatus I have substituted a vessel of thin copper instead of the upper part of the glass vessel A_1. This arrangement answers the purpose excellently.

[4] And also in A_1, which is of the same size. This condition is, however, by [illegible] indispensable. A_1 can be greater or smaller than A, only the [illegible] of A and A_1, B and B_1 are proportional to each other.

travellers in the work of exploration." "On the best means of turning to better account for science and commerce the work of Italian explorers." "On the importance of establishing commercial stations in the Barbary States as a means of gaining access to the Sudan"; and "On Geographical Education."

MR. RIVETT-CARNAC sends us a handy reprint of his valuable paper "On the Stone Implements from the North-Western Provinces of India," originally published in the *Journal* of the Asiatic Society of Bengal. The striking resemblance that the remains of the Palæolithic and Neolithic ages bear to each other wherever found in the Old and New Worlds, has often been commented on, and receives fresh illustration from the three plates of celts, arrowheads, hatchets, hammers, weights, and other objects, accompanying the brochure. These specimens are lithographed from photographs, and all made to scale, whereby their value is greatly enhanced for the comparative study of similar objects elsewhere. It is pleasant to learn that the best specimens have all been presented to the British Museum, while casts of some unique types peculiar to India have been made for the chief museums of India, Europe, and America, and even for some private persons interested in prehistoric research.

EVEN in Rome the aërial disturbances caused by the Krakatoa explosion were clearly indicated on the registering barometers. On examining the curves of the Richard barograph Prof. Tacchini found that, although the daily curves followed regularly in accordance with the normal barometrical conditions in Europe, those of August 27, 28, and 29, 1883, betrayed slight indentations, which, without changing the daily record of the pressure, show that for short intervals its precision oscillated abruptly, owing to the passage of the above-mentioned waves. These barometrical oscillations occurred at the following times:—12.7 of the 27th, 5.6 a.m. of the 28th, 1.48 a.m. of the 29th, and, lastly, about 4 p.m. of the same day. The time of the volcanic explosion was determined by Tacchini by the report of S. Raffo, captain of the Genoese brigantine the *Adriatic*. S. Raffo states that during the night of August 26-27 continual peals were heard, and that at eight o'clock next morning he heard one of extraordinary violence, accompanied by a shock to the vessel, which was then in 10° S. lat. and 105° E. of Greenwich. Tacchini accordingly concludes that the time of the explosion corresponded with 1.30 a.m. of the 27th at Rome. From these data he finds that the wave reached Rome from Krakatoa by the west, leaving the volcano at a velocity of 277 m. per second, and that moving in the opposite direction at a velocity of 296 m. He further calculated by the observations made at Rome that the complete atmospheric circuit round the globe was effected by the east, leaving Rome at a velocity of 295 m., and of 318 m. by the west. Captain Raffo has forwarded to Rome a quantity of the dust collected on board the ship on that day.

WE learn from *El Liberal* of Madrid, July 23, that D. Auguste Arcimis has been observing sunset phenomena very similar to those witnessed last autumn and winter. He has besides noticed an extremely brilliant silver-white corona around the sun, having a horizontal diameter of about 48°.

THE Afghan Frontier Commission will, we are glad to learn, include a geologist and native botanist, as well as three surveyors. But, as Mr. Sclater suggests in the *Times*, it is to be hoped that the scientific staff will also include a zoologist or at least a zoological collector. Mr. Sclater writes:—"The country to be passed through by the Afghan Frontier Commission, although probably in the main part bare and arid, is of the deepest interest to zoologists, as being situated nearly on the boundaries of the Palæarctic and Oriental regions. The numerous Russian and American Surveys which have been sent out of late years with similar objects have always given a place in the scientific staff to zoology as well as botany and geology. There is no reason, it seems to zoologists, why our Government should not follow such an excellent example, especially when there will be no difficulty among the numerous Indian officers who are now interested in zoology in finding a suitable person. Let me, therefore, express a hope in the name of British naturalists that a zoologist will be added to the 'scientific staff' of the Afghan Frontier Commission."

WE are glad to notice that the new St. Paul's School at Hammersmith includes physical and chemical laboratories.

IN a lecture on the Olympic Festival by Dr. A. Emerson at Johns Hopkins University, the lecturer stated that in the Olympic games uniform training, early registration, and fair play were required of the athletes, under penalty of exclusion, or, if fraud was discovered too late, of heavy fines. Dr. Emerson gave the following as the ancient and modern records of running and leaping:—

Day's run: Good Greek record, 150 km.;
Good modern record, 168 km.
Long running jump: Best Greek record, 55 feet;
Best modern record, 49 feet (Engl.) 3 inches.

As the victors in the horse-races, Dr. Emerson stated, were the registered owners of the animals, such victories could be and often were won by women.

MR. H. M. STANLEY arrived in England from the Congo on Monday.

THE Bangkok Correspondent of the *Times* telegraphs that Mr. Holt Hallett and his party have reached Bangkok after an arduous expedition, lasting five months and thirteen days, from Moulmein to Bangkok through North Siam. Mr. Hallett succeeded in reaching his destination, though severely fatigued. He will return and spend one month in England, and it is hoped that the sea voyage will recruit his health. On his arrival in London he will submit a preliminary report to the Chambers of Commerce and the Geographical Society, and will return and continue the surveying operations in November. The work completed comprises the surveying of over 1500 miles, the determination of the position of the Shan ranges, and a large series of observations on the vocabularies of the aboriginal races and the histories of the several Shan States. A mass of information throwing light on the interior of Indo-China, especially of North Siam, was gathered. The reception of the expedition was from first to last excellent. This fact was due mainly to the favourable attitude of the natives and the tact and conciliation of the leader.

THE Normanic coast of the Kola peninsula will be visited this summer by several explorers. MM. Enwald and Edgren will investigate its natural history; M. Kushcleff the fishing along the coast; M. Hartzenstein has undertaken researches into the fauna and flora of the neighbouring sea; M. Istomin is engaged in ethnographical researches; and M. Abels, of the Central Physical Observatory, is now at Archangel, in order to establish meteorological observatories in the north.

AT Forio, in the island of Ischia, a powerful shock of earthquake was felt on the 23rd inst. The tremor was proceeded by loud subterranean rumbling like thunder, or the roar of artillery. The exact time when the event took place was twenty minutes to one o'clock p.m. Fortunately, the phenomenon lasted but momentarily, and passed off without doing any material damage to property, or causing any loss of life. An earthquake also occurred at Massowah on the 24th. Nearly all the houses in the town were destroyed or damaged by the shock. All the ships in the harbour were seen to rock violently.

THE employment of acupuncture and cauterisation by Chinese doctors forms the subject of an article in one of the last numbers

of the *North China Herald*. A native public writer not long since claimed that a skilful physician in this department of medicine could cure such diseases as imbecility, fits, cholera, &c. The principle of cauterisation is simply that of counter-irritation; and the English writer bears personal testimony to its efficacy in the case of a slight sunstroke, although the operator was a simple Manchu peasant, and instrument a couple of copper coins. Very extraordinary cures are attributed to acupuncture by the Chinese. It is first performed in the hollow of the elbow of each arm. If the puncture draws blood there is no danger, but if no blood appears the case is regarded as very grave. But before abandoning the sufferer, puncture of the abdomen is tried. Seizing a handful of flesh, the operator drives the needle right through it, and then draws it backwards and forwards a few times. If the patient manifests any sense of pain, or if any blood is drawn, a poultice of eggs and buckwheat flour is applied over the puncture, and recovery is regarded as almost certain; but if no pain is felt and no blood flows, the case is declared hopeless, and the sufferer is left to die. The case is then quoted of a young Chinese, educated abroad, who was attacked with cholera; his extremities became cold, and cramp set in in a somewhat alarming manner. The barber-surgeon who was called in commenced by running a needle into the pit of the patient's stomach, a jet of very dark blood following; he then punctured the calf, the two breasts, and the forehead of the sufferer, freeing a certain quantity of blood at each prick. The relief is said to have been instantaneous, and in two days recovery was complete. The Chinese explanation of this treatment is that, when the blood is in the poisoned condition which induces the choleraic symptoms, it becomes thick, and accumulates in certain portions of the body. A clever surgeon knows exactly how to put his finger on the particular spots, and, by skilfully "opening the mouth of the heart," as the operation is called, sets free the poisoned fluid which causes all the mischief. It is noteworthy that faith in the efficacy of this mode of treatment is not confined to the masses, but is shared by Chinese who have been abroad and have had ample experience of Western medical practice.

MR. JAMES HOPPS, Indian Engineering College, Cooper's Hill, writes us with regard to his paper on the electric resistance of metals, read before the Physical Society (NATURE, vol. xxx. p. 283), that an *increase* of resistance on *uncoiling*, and a *decrease* on *coiling* takes place with lead, copper, German silver, aluminium, and magnesium, and also during the first few operations on soft iron. An *increase* almost invariably follows coiling and uncoiling with zinc, but the effects of coiling vary from $\frac{1}{2}$ to $\frac{1}{10}$ of the effects of uncoiling. The full paper will appear in the Society's *Proceedings*.

THE additions to the Zoological Society's Gardens during the past week include a Malbrouck Monkey (*Cercopithecus cynosurus* ♂) from West Africa, presented by Mr. J. H. Harling; a Cape Sea Lion (*Otaria pusilla*) from South Africa, presented by Mr. John Hunt; two Daubenton's Curassows (*Crax daubentoni* ♂ ♀) from Venezuela, a Common Guinea-Fowl (*Numida meleagris*), British, presented by Mr. W. Burch; two Indian Kites (*Milvus govinda*) from Eastern Asia, presented by Mr. W. Jamrach; a Barn Owl (*Strix flammea*), European, presented by Mr. G. H. Garrett; three Angulated Tortoises (*Chersina angulata*), two Geometric Tortoises (*Testudo geometrica*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; two Smooth Snakes (*Coronella lævis*), European, presented respectively by Mr. W. H. B. Pain and Mr. F. H. Jennings; two Black-tailed Deer (*Cariacus columbianus* ♂ ♀) from North America, two White-backed Piping Crows (*Gymnorhina leuconota*) from Australia, two Common Cormorants (*Phalacrocorax carbo*), British, deposited; two Red-capped Parrots (*Pionopsitta pileata*) from Brazil, a White-bellied Sea-Eagle (*Haliaëtus leucogaster*) from Australia, a Mohr Gazelle (*Gazella mohr* ♀) from North Africa, a Violet-necked Lory (*Eos riciniata*) from Moluccas, a Black Tortoise (*Testudo carbonaria*), a Common Boa (*Boa constrictor*) from South America, two Electric Eels (*Gymnotus electricus*) from British Guiana, purchased; three Elliot's Pheasants (*Phasianus ellioti*), bred in England; a Mule Deer (*Cariacus macrotis*), a Mesopotamian Fallow Deer (*Dama mesopotamica* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN

SCHMIDT'S VARIABLE-STAR IN VIRGO.—On June 6, 1866, Schmidt remarked, east and south of Spica, a star which he at first estimated 4 m., subsequently 5·4, not found in Argelander's *Uranometria*; it was much better visible than *i* Virginis, the reddish-yellow fifth magnitude south of Spica. By observations during the next fortnight its light appeared to have slowly diminished, nevertheless on June 19 it was still visible with the naked eye, though there was strong moonlight. On examination of the catalogues, &c., it was found that Lalande estimated it 6·7 on May 10, 1795; Piazzi calls it 6·7 and 7 in the *Storia Celeste*, not 8 as in the printed catalogue: Bremicker entered it of the seventh magnitude on his Berlin chart, while Lamont calls it 8 m. in Zone 355, observed on May 22, 1846. Heis has it 6·7, while Gould says, "Var. 5½-6¼." Houzeau judged it a sixth magnitude at the date 1875·11. We have thus evidence that it has been pretty conspicuously visible to the naked eye, while, on the authority of Bremicker and Lamont, it has been at other times beyond average unassisted vision.

Schjellerup has raised a point of much interest in connection with this star. There has been a difficulty in identifying satisfactorily Ptolemy's 19th star in Virgo, which he calls a fifth magnitude (ι in his notation). Baily, in his notes to his edition of Ptolemy's Catalogue, published in vol. xiii. of the *Memoirs* of the Royal Astronomical Society, writes: "The star 68 Virginis agrees with the position given by Ptolemy; but it is difficult to make it accord with the description, as being in the 'latus sequens' of the quadrilateral figure." Schjellerup, in his translation of Sûfi, remarks: "A l'endroit où, selon la description détaillée que nous a fournie Sûfi, doit se trouver la 19e étoile, il n'y à aucune étoile aujourd'hui visible à l'œil nu, selon *Uranometria Nova* d'Argelander, pendant qu'il s'accorde très-bien avec celui de Lalande 25086, étoile qui est entre la sixième et la septième grandeur. En faisant la revision de cette note, je me rappelai l'étoile variable au sud-est de α Virginis, dont nous a donné avis M. Schmidt dans le nr. 1597, *Astronomische Nachrichten*. Quelle ne fut ma surprise en m'apercevant de l'identité entre cette variable et la 19e de Sûfi?"

This identification, however, is hardly so certain as may at first sight appear. Schmidt's star is in the Greenwich Catalogue for 1872, which gives its position for 1880·0—

Right Ascension 202° 4′·4 ... ... Declination − 12° 35′·9

Ptolemy professes to have reduced his catalogue to the first year of Antoninus, A.D. 138, though it is well known that his longitudes are in defect to the amount of about 1° for that epoch. Unfortunately, for the 19th star of Virgo, though the longitudes agree, the latitudes given in the various editions of the Almagest and by Sûfi are materially different. Baily has it − 3° 0′, with a note that in the Venice edition in Latin by Liechtenstein, in 1515, it is + 0° 20′, which he thought might arise, as regards the difference in amount, from mistaking γ for γ′. While in the two manuscript copies of Sûfi (who adopted the positions of the Almagest, adding 12° 42′ to the longitudes) the latitude is − 1° 20′.

To reduce the Greenwich position for 1880 to the year A.D. 138, we have in the usual notation—

$$A = 168° 47'·3 \ \dots \ A' = 191° 0'·8 \ \dots \ \theta = 9° 40'·6;$$

with which the position for Ptolemy's epoch is found to be—

Right Ascension ... 179° 36′·0 Declination ... − 3° 5′·4;

and assuming the obliquity of the ecliptic to be 23° 41′·8, we have—

Longitude ... 180° 53′ Latitude ... − 2° 59′

The longitude of the 19th of Virgo is apparently 178° in all the editions of the Almagest, and the latitude differs 1° 39′ from that assigned in the manuscripts used by Schjellerup.

If we similarly reduce the Greenwich position of 68 Virginis to Ptolemy's epoch, we find—

Longitude ... 178° 53′ Latitude ... − 3° 14′

and Baily's identification of the 19th of Virgo would thus appear the more satisfactory, at least if the reading he has adopted for the latitude is admitted; still there is the difficulty pointed out in his note which is given above; 68 Virginis is estimated a sixth magnitude both by Argelander and Heis.

In 1879 Mr. S. W. Burnham discovered that this star is a very close double, the mean of his measures giving—

1879·39 Position 81°·2. Distance 0″·47. Magnitude 6·1 and 6·6.

He remarks that hitherto close double-stars have not been found among the variables. It remains to be ascertained whether, if the variability of Schmidt's star be established, both or only one of the components vary.

A New Comet.—A telegram notifies the discovery of a comet by Mr. E. Barnard, on the 16th inst., though, probably from interruption from unfavourable weather in verifying it, the announcement appears not to have been made for several days subsequently. The position given is as follows:—

July 16 at 15h 21m 2s G.M.T. ... R.A. 237° 40′ 0″ ... N.P.D. 127° 9′ 52″

It would be well within reach of the observatories of Southern Europe. From a telegram received at Dun Echt, Dr. Copeland conjectures that the comet has been seen at Melbourne, Madras, and Cape Town; Prof. Krüger has no allusion to this in his note in the *Astronomische Nachrichten*. The comet's motion is stated to be slow.

SCOTTISH METEOROLOGICAL SOCIETY

THE half-yearly general meeting of the Society was held on Monday, July 21, in Edinburgh, Mr. Milne Home in the chair.

Mr. Buchan read the report from the Council. As regards the Society's stations, one has been added since last general meeting at Glencarron, in Ross-shire. It has been established by Lord M'Laren, and from its position it is one of the most important additions recently made to the Society's stations. The effort made to increase the membership has been already attended with marked success. The membership now numbers 601. The first number of the new series of the Society's *Journal* is now mostly in type, and will shortly be in the members' hands. It has been arranged that in future the proceedings will appear annually in March. The Council referred with much satisfaction to the successful manner in which Mr. Omond and his assistants carry on the observations on Ben Nevis. The discussion of the past observations shows that paramount importance must be assigned to a continuous record, not only of the barometer, but also of the temperature, humidity, wind, cloud, and precipitation, on account of their intimate relations to the barometric fluctuations and to coming changes of weather. Every effort will therefore be made to secure to science a continuous hourly record of the weather phenomena of Ben Nevis. Arrangements have been made for the completion of the Observatory buildings during the course of this summer. A beginning of the work is made to-day (July 21), and it is expected that the whole will be finished some time before October. The new buildings include a tower, on the top of which will be placed anemometers, specially designed by Prof. Chrystal and Prof. Crum Brown, for registering the direction, velocity, and pressure of the wind, a correct knowledge of which is of supreme importance in carrying on the scientific and practical inquiries aimed at in the establishment of the Observatory. To the expenses connected with the erection of the anemometers a grant of 50*l*. has been made by the Committee of the Government Research Fund. An exit from the building has been made in the upper part of the tower, which will enable the observers to make outside observations during the winter months, on many occasions when they could not otherwise be attempted. The Council regret to intimate that their application to the Treasury for a grant in aid of the establishment of the Marine Station at Granton was not successful. Notwithstanding the refusal of the Government to give assistance, the Marine Station, to which the Society contributes 300*l*. a year from the Fishery Fund, was established in April. There is every probability that the subscriptions from the general public will shortly permit of very desirable extensions being made to the further equipment of the station. In response to an offer by the Scottish Sea-Fishing and Curing Company, Mr. Pearcey, of the *Challenger* Office, made observations on a cruise in the ship *Energy* in the North Sea, between Shetland and Norway. The specimens obtained during the cruise, and the observations made, are now under consideration.

A paper was read by Mr. Buchan on the meteorology of Ben Nevis, which we hope to give in an early number.

Dr. Arthur Mitchell described a new instrument for collecting continuously any cosmic dust, volcanic dust, or other impurities mechanically suspended in the atmosphere, the essential part of the instrument being a series of filters of fine platinum wires, through which the air is continuously drawn by an aspirator.

A report of the work done at the Scottish Marine Station at Granton was submitted by Mr. J. T. Cunningham, naturalist in charge. He detailed the nature of the work since the opening of the Station in April. The method of working in the yacht *Medusa* was then described. The position of the yacht is ascertained by means of bearings at the time when the dredge or other apparatus is put down or taken up. At these points the depth of the water and the nature of the bottom are ascertained, and various physical observations taken, including the temperature of the air, and that of the sea at the bottom, at the surface, and at intermediate depths; samples of sea water are also secured from different depths. When the dredge or trawl is hauled on deck, the contents are examined and the relative abundance of the animals and Algæ noted down. Some of the specimens are preserved on the spot, and a number of them are brought alive to the Station, and placed in the floating cages or in aquaria in the laboratory, so that they may be more minutely examined in the living state, and form a stock which may be drawn upon for purposes of special research. The products of the fine tow-nets are treated in the same way; a microscope is always on board, and in calm weather the minute specimens can be examined in the cabin. Samples of the contents of the tow-nets are preserved and labelled on board, and the remainder are brought back to the Station alive and examined in the laboratory. The results of one day's work at sea usually provide material for two or three days' work on shore. The work of dealing with the preserved collections, identifying and separating the animals, goes on continuously at the Station. The materials for faunological and systematic zoological work soon became abundant, and in the inquiries continuously carried on special attention is given to identify the numerous kinds of fish spawn, both floating and attached, which occur in the Firth of Forth and neighbouring parts of the sea. In order that the systematic and general work of the Station might not be neglected, the services of Mr. John Henderson as zoologist have been secured. The study of the Algæ has been energetically carried on by Mr. Rattray. The work carried on by Mr. Mill has been chiefly physical. A regular system of meterological observations, both on land and in the "ark," has been set on foot. Up to the present time three biologists have availed themselves of the opportunities afforded by the Station for research—Prof. W. A. Herdman, University College, Liverpool; Prof. Haycraft, Mason's College, Birmingham; and Mr. J. R. Davis, University College, Aberystwith.

Mr. Hugh Robert Mill read a paper on the tidal variation of temperature at the Marine Station. He detailed the nature of the experiments, these including hourly and half-hourly observations by night and by day on three occasions, extending in all to ninety-seven hours. The results show interesting relations between the temperature, the time of day, and the state of the tide. Without attempting to generalise, the following facts observed in each series of observations may be stated:—The surface temperature rose when the air temperature rose, and fell when it fell, with no very apparent reference to the tides. The curve for bottom temperature also followed that of air temperature, though to a slight extent; but the crest of the heat wave was retarded for several hours, and the tide produced great modifications in the temperature. When the tide flowed early in the morning it cooled the bottom temperature; when it entered at a later hour it raised it. By day the bottom temperature was lower than that of the surface; by night it was equal to it or slightly higher. The causes which produced these various effects must be very complex. The contour of the bottom of the quarry, the rates of influx of the tide, the direction of the currents it originates, the duration and period of the sunshine, the direction of the wind, the heating of the sand by the sun and its cooling by radiation, the heating and cooling of the surface water by radiation, and

the bottom water by conduction and convection, must all be taken into account before a true explanation could be arrived at. It is intended to devote special attention to the effect of radiation on the sand, and of the heated or chilled sand on the tidal water which flows over it, it being probable that it is in this way the key to the curious tidal perturbations of temperature may be found.

THE PHILOSOPHICAL SOCIETY OF GLASGOW

THE *Proceedings* of the eighty-first session have just been published in the form of a volume of 428 pages, and consisting of twenty-four papers, three plates, and a map. The papers are: an address on some of the chemical industries of the country, by Mr. R. R. Tatlock, President of the Chemical Section; on technical education, by Mr. Henry Dyer, C.E.; a discussion of Mr. Dyer's paper, by Mr. E. M. Dixon, B.Sc.; an introductory address on the definition and scope of geography and ethnology, by Dr. W. G. Blackie, President of the Geographical and Ethnological Section; on the use of litmus, rosolic acid, methyl-orange, phenacetolen, and phenolphthalein as indicators, parts ii. and iii., by Mr. Robert T. Thomson; on an easy way of determining specific gravity of solids, by Dr. Dobbie and Mr. John B. Hutcheson; note on Mr. Joseph Whitley's centrifugal mode of casting steel plates for shipbuilding, &c., by Dr. Henry Muirhead, President; notes on Cleopatra's Needle, by the President, on the occasion of presenting a large bronze model of the Needle to the Society; on a new method of measuring the heat-conducting power of various materials, such as cotton, wool, hair, &c., by Mr. J. J. Coleman; on a new thermometer or thermoscope, by Mr. Coleman; on the measurement of electric currents and potentials, by Sir William Thomson; a sketch of the life and work of Dr. Allen Thomson, by Dr. McKendrick; note on modern forms of the microscope, by Dr. W. Limont; on the chief features of the physical geography of China, by Rev. A. Williamson, B.A., LL.D., Missionary in China; on the recent progress of chemistry at home and abroad, by Prof. J. J. Dobbie; on the analysis of commercial carbonate of potash, by Robert Thomson; on a new process for the separation of nickel and cobalt, by Dr. John Clark; on an endless solenoid galvanometer and voltmeter, by Prof. James Blyth; on the chemical composition of the methyl and ethyl alcohols, by Dr. Otto Richter; on the Island of New Guinea, by Dr. W. G. Blackie, illustrated by a map published by permission of the Royal Geographical Society; on the consumption of smoke, especially in great cities, by Mr. A. Pinkerton; on rickets in Glasgow and neighbourhood, and the relation of the disease to food and water used by the inhabitants, by Mr. James Thomson, F.G.S.; and the Graham Lecture by the late Dr. R. Angus Smith, prepared for publication by Mr. J. J. Coleman.

The last paper is probably the most interesting and important of all, inasmuch as it contains many unpublished letters of Thomas Graham, so full of information as to his work and the circumstances in which his work was done that it cannot fail to attract the notice of all engaged in physico-chemical research. The paper has a mournful interest also as being the last from the late Dr. R. Angus Smith. It will be published separately, in a small volume, for the use of those who desire to have a memorial of Thomas Graham.

The Society has a membership of 690. Its work is carried on not only by the parent Society, but by five sections—Chemistry, Biology, Architecture, Sanitary Science and Social Economy, and Geography and Ethnology.

SCIENCE IN RUSSIA

THE Kazan Society of Naturalists continues its useful work of exploration. The last volume of its *Memoirs* (*Trudy Obschestva Estestvoispytateley pri Kazanskom Universitete*, vol. xii.) contains two papers by the late M. Shell, on the botanical geography of the provinces of Ufa and Orenburg, being a list of 1054 Spermatophores already known from these two regions which have an intermediate flora between that of South-Eastern Russia and that of the Caspian Steppes. A most useful addition to the knowledge of the flora of these provinces is contained in the second paper by the same author, which gives a list of no less than 511 species of Sporophores (28 Vascular plants, 49 Mosses, 2 Charæ, 181 Algæ, 94 Lichens, and 157 Fungi). The importance of this addition may be seen from the fact that, before M. Shell's work, only 39 species of Sporophores were known from these two provinces. It is worthy of notice that M. Shell has found among the Algæ the *Asterionella formosa*, Hassel, which has been discovered in England and was found on the Continent only by Brébisson in France, and by Heiberg in Denmark. The death of M. Shell in 1881 at Vilno was a great loss to Russian science. In the same volume M. Bekarevitch publishes his "Materials for the Flora of Kostroma," being a list of 514 species of Phanerogams and 18 Cryptogams. M. Flavitzky publishes his researches into the pitchers of different Conifers. The author has studied the deviations of their planes of polarisation, and has found that the value of the angle of deviation is quite characteristic for different pitchers; it varies from $-42°\cdot2$ (*Pinus abies*) to $-13°\cdot1$, $-10°\cdot9$, and $-9°\cdot6$ for the *Pinus sylvestris*, *P. cembra*, and *Abies sibirica*, and from $+9°\cdot1$ to $+27°\cdot2$ for the *Abies balsamea* and *Larix europæa*. We must notice also the elaborate researches, by A. Dogel, into the structure of the retina of the Ganoid fishes. These researches fill a gap which was pointed out many times; they are accompanied by excellent plates engraved at Leipzig.

The minutes of proceedings (*Protokoly*) of the same Society are especially interesting for mathematicians, as they contain a number of notes by MM. Maximowitch, Klark, and others. They are followed by papers on the motion of liquids in elastic tubes, by Prof. Gromeka; on the ichthyology of Kazan, by N. Varpakhovsky; and on the dangerous insects of Samara, by E. Peltzam.

The new volume of the *Memoirs* of the Kharkoff Society of Naturalists (*Trudy Obschestva Ispytateley Prirody pri Kharkovskom Universitete*, vol. xvii.) contains a paper by N. Koultchitzky, on the structure of the "Grandry corpuscles," being a description of that special form of corpuscle by which the nerve is terminated in the tongue of the duck, which M. Grandry distinguished in 1869 from the corpuscles of Herbst (or Pacini's with other animals). The paper is accompanied by three lithographed plates. M. Byeletzky's posthumous paper, on the physiology of the aërial or natatory bladder of fishes is a very elaborate memoir on this subject. The author, who has taken notice of nearly all the researches made in the same direction during more than a century, gives a detailed anatomical sketch of the bladder, and a summary of all known as to its contents. His own researches have been made on fifty-four individuals belonging to the following six species:—*Cyprinus carpio*, *Carassius vulgaris*, *Tinca vulgaris*, *Abramis brama*, *Idus melanotus*, and *Perca fluviatilis*. The gases contained in the bladder are: nitrogen, from 81 to 96 per cent. of the whole (sometimes even 98); oxygen, mostly less than 10 per cent., and very seldom from 15 to 20 per cent.; and carbonic acid from 2 to 5 per cent., falling to 0·6, and very seldom reaching more than 7 per cent. The contents of carbonic acid depends very much upon the conditions which the fish has been kept in before the experiments; but it stands in no correlation at all with the contents of oxygen. The amount of both may be simultaneously small, or greatly above the average. As to the origin of the gases in the bladder, the author indorses the views of Configliachi (Schweigger's *Journal für Chemie und Physik*, Band i. 1811), and concludes that they are not indebted for their origin either to digestion or to the supposed "swallowing" of air on the surface of the water; individuals kept for months under water, without having the possibility of reaching its surface, having been found to have the same composition of gases in the bladder as free individuals. It would rather seem that, with the raising of the fish on the surface, which is accompanied by a diminution of atmospheric pressure, a part of the gas is expelled from the bladder. The most probable origin of the gases in the bladder seems to be —Configliachi said—that the air contained in the water and entering into the mouth of the fish is in some way (perhaps in that pointed out by Erman) eliminated from it; it is dissolved in the blood of the gills, and the oxygen is slowly assimilated by the blood; while the remainder, that is, nitrogen and some oxygen which has remained dissolved, are secreted from the blood into the bladder. This is also the opinion of M. Byeletzky, who considers that blood, as also the lymph, is the source whence the gases of the bladder originate. Contrary to Configliachi's opinion, they are not secreted, however, by the "red corpuscles," but rather by the capillary vessels of the mucous membrane of the bladder; such was also the opinion of Rathke and Johann Müller; however, the argument by which they tried to establish this view cannot be longer held. In

a paper on the microscopic structure of the coal of the Doltz basin, M. Jenjourist shows that the coal contains remains of Sigillariæ and Lepidopendrons, while several Russian geologists are inclined to consider it as having originated only from marine Algæ. M. Dybovsky contributes to this volume a description of a new species of fresh-water sponge from Southern Russia, which is closely allied to the *Dosilia baileyi* of Mr. Carter, and to which he gives the name of *Dosilia stepanowii*; it is figured in a plate. Finally, M. Shevyreff gives a list of *Hymenoptera terebrantia* of the Governments of Kharkoff and Poltava; and M. Yaroshevsky publishes his fifth supplement to the list of Diptera of Kharkoff.

The last two volumes of the *Memoirs* of the St. Petersburg Society of Naturalists (*Trudy Sanctpeterburgskago Obschestva Estestvoispytateley*, vol. xiii. fasc. 2, and vol. xiv. fasc. 1) contain, besides the minutes of proceedings (which unhappily do not go further than March 1883), several valuable papers. Geology is the most favoured branch. Thus we find in vol. xiii. an interesting paper on the waterfalls of Northern Esthonia, by P. N. Vemikoff. The orography of the country whose Silurian deposits are cut towards the north by the abrupt terrace of the Glint, the lower parts of which contain looser strata easily destroyed by the water (as in the Niagara), favour the development of waterfalls, the chief of which are described by the author. In the same volume MM. Koudryavtseff and Sokoloff publish a geological description (with a geological map) of the district of Kromy in Orel. The Quaternary formations are represented by the "black earth," loess, and mighty sheets of boulder-clay which cover the chalk, the Jurassic clays, containing spherosiderite, and the Devonian limestones, marls, and dolomites, appearing in the north. The paper is accompanied with a map on a large scale. In vol. xiv. we find a very interesting orographical sketch of the Kola peninsula, by N. Koudryavtseff. The author has devoted much attention to the leading features of this tableland, and the modifications its surface has undergone under the action of the ice-sheet of the Glacial period. The structure of the mountains; the parallelism of the valleys; the glacial erosion, which has covered the whole of the country with numberless depressions running in the direction of the glacial striation, and producing what might be called "telescopic striation"; the finer glacial striæ, which run north and south, or north-north-west to south-south-east; the "glacial landscape" of the country; and finally its upheaval, are dealt with by the author. Several indications led the author to admit that the peninsula is rapidly rising up, the surest of them being the find of colonies of Balanides at a height of 8 metres above the sea, and the discovery of the *Buccinum undatum* (which still inhabits the White Sea), together with broken shells of Brachiopoda and Lamellibranchiata, about 280 feet above the present sea-level, at Kandalaksha. N. A. Sokoloff contributes to the same volume a note (with a plate) on the find of teeth of *Mastodon arvernensis* in the Crimea, at Zamruk, which would imply a wider extension of Pliocene in the yet unexplored steppes of the peninsula; and on the find, also in the Crimea, of teeth of *Hipparion gracile*, which was so widely spread during the Tertiary period from the prairies of the Missouri to the Himalayas. We notice also a note by P. P. Kudryavtseff, on prehistoric man on the Oka; and another note by M. Polyakoff on the bottom-moraine at Wiborg, in Finland.

In other branches of science we have to mention a sketch of the Phanerogam flora of the Government of Minsk, by W. Paszkewicz (vol. xiii.). It contains 958 species, the whole number reaching probably about 1000; 40 of them are new for this region. In vol. xiv. we find a note by M. Szihowsky on the chemical constitution of different parts of the *Zea Mays*, and two preliminary reports, botanical by A. Krasnoff, and zoological by A. Nikolsky, about explorations in the Altaï Mountains. The collections of 720 Phanerogams and 100 Cryptogams, which have been brought in by M. Krasnoff, will surely yield interesting data. As to M. Nikolsky, he gives a lively sketch of the fauna of the Altaï, followed by a list of observed species: 50 mammals, one of which, *Talpa altaica*, is new; 169 birds, a few reptiles and amphibia, and 16 fishes. A plate gives the comparison of the *T. altaica* with the *T. europea*.

RECENT MORPHOLOGICAL SPECULATIONS[1]

III.—*Non-segmented Animals*

THERE are certain groups of animals about whose systematic position naturalists never seem able to remain long agreed. These groups are changed from place to place in our schemes of classification; and often each new discovery seems to confute a current theory only to confirm that which preceded it. More than any other groups, the Polyzoa, Brachiopods, and Mollusks have been shifted from point to point, and it seems almost too much to expect that they have even now found a permanent resting-place.

The Polyzoa were brought into connection with "Mollusks" more than fifty years ago, when Milne-Edwards exhibited their supposed affinities with Ascidians, and their Molluscan affinities were more fully admitted when Von Siebold compared the Polyzoan lophophore and tentacles with the arms of a Brachiopod. Milne-Edwards, in combining Polyzoa and Tunicates in his new group Molluscoida, argued the identity of the type in every detail of structure, and Huxley ("English Cyclopædia," 1855), laying more weight than previous writers had done on the affinities of Polyzoa with Brachiopods (as Mr. Albany Hancock was perhaps the first to suggest) definitely included this last class also in the group Molluscoida. The Brachiopods seemed, in the light of that time's knowledge, to take a very natural position among the "neural Mollusks," between the Polyzoa on the one hand and the Lamellibranchs and the Pteropods on the other (*Proc. Roy. Soc.* 1854, p. 117).

But in the course of the next ten years Kowalevsky's discovery of Loxosoma seemed to supply a link between the Polyzoa and Worms, and Gegenbaur, and afterwards Haeckel, emphasised this relation, and finally included the Polyzoa in the latter group. The Tunicata had by this time obtained, through Kowalevsky's researches, an established position far removed from their former allies in the "Molluscoida," and Gegenbaur now analysed more critically the differences between Polyzoa and Brachiopods, and (denying that either had any affinity with Mollusks) maintained the eminently isolated position of Brachiopods, and asserted that their arms could no more be compared with the tentacles and lophophore of Polyzoa than these could with the branchial tufts of the Tubicolæ. The discovery by Kowalevsky (1874) of the apparently segmented larva of Argiope, &c., seemed to reveal almost obscured genetic relations with the Chætopods, and at the same time Morse, working chiefly on Lingula, argued elaborately that the Brachiopods are much modified Annelides. Ray Lankester, on the other hand, upheld the Molluscan affinities of both Polyzoa and Brachiopods, and Huxley, in his "Anatomy of Invertebrates," kept the three groups in close juxtaposition. Lankester compared Rhabdopleura minutely with the embryo of Pisidium (*Phil. Trans.* 1874), and maintained the common origin from a primitive ciliated girdle of the gill-filaments of Lamellibranchs, the lophophore of Polyzoa, the arms of Brachiopods, the tentacles of Phoronis, the velum of embryo Mollusks and of Rotifers, and the ciliated proboscis of Gephyrea. Huxley ("Invertebrates," p. 674), influenced on the one hand by Lankester, and by Steenstrup and Morse on the other, proposed to combine Polyzoa and Brachiopods under the name *Malacoscolices*, to indicate relationship both with Mollusks and with Worms. Lastly, Caldwell (*P. R. S.* 1882), by his researches on Phoronis, has thrown new light on the structure of both Polyzoa and Brachiopods, and, in Lankester's words ("Encycl. Brit.," Art. "Mollusca," 1884), "has established the conclusion that the agreement of structure supposed to obtain between Polyzoa and true Mollusca is delusive; and accordingly they, together with the Brachiopoda, have to be removed from the Molluscan phylum."

We may examine this last important view more closely, and try afterwards to discuss the probable ancestry of these three much-debated classes.

Actinotrocha, the larva of Phoronis, is, according to Caldwell, a perfect and typical trochosphere. The larvæ of Brachiopods and Polyzoa are trochospheres in which, by a shortening of the "dorsal" surface, mouth and anus have been approximated, and the ventral surface has been enormously distended. The same change takes place, and to an even greater extent, in the "metamorphosis" of Phoronis: the adult animal has both mouth and anus situated at one end of a long body; the line joining them is the contracted dorsal surface; an epistome, said to be the persistent præ-oral lobe of the larva, lies between mouth and anus; a lophophore, whose new tentacles are added on either side of the median dorsal line, surrounds the mouth; within its concavity, on either side of the anus, lie two ciliated pits, whose homologue is found in Rhabdopleura. A single pair of nephridia exist. The body-cavity is traversed by mesenteries, one of which is ventral, and attaches the outside of both descending and ascending limbs of the alimentary canal to the body-wall; two are lateral, and pass from the side of the stomach to the body-wall, dividing the

[1] Continued from p. 227.

cavity into two anterior chambers and one posterior; and lastly a transverse septum shuts off the space within the epistome and tentacles from the rest of the body-cavity. The nephridia open into the posterior chamber of the body-cavity on the sides of the lateral mesentery. At no stage, either in the embryo or the adult, is any trace to be found of segmentation.

The parallelism between Phoronis and Brachiopoda is full and clear. An ectodermal post-oral nerve-ring exists in both. The body-cavity of the præ-oral lobe is in both separated from the rest of the body-cavity by a septum. The tentacles are arranged and developed similarly in both. In both the nephridia have the same relations and the alimentary canal is divided into the same four parts. And in both the præ-oral lobe of the larva is represented in the adult by an epistome. The Polyzoa, though immensely simplified in structure, seem undoubtedly to be built upon the same plan; and Caldwell considers it probable that the epistome of Endoproct and Hippocrepian Polyzoa and the so-called foot in Rhabdopleura represent, like the epistome of Phoronis and Brachiopods, the præ-oral lobe.

Mr. Caldwell closes the abstract of his yet unpublished paper with a remark upon the affinities of the Gephyrea. We know nothing to show that Sipunculus and Phascolosoma are not referable to the same type of structure as Phoronis, Brachiopoda, and Polyzoa.

But as regards the types from which all these mutually-connected forms sprang, we know little or nothing, and we look in vain for an unsegmented worm which shall show clear affinity with them.

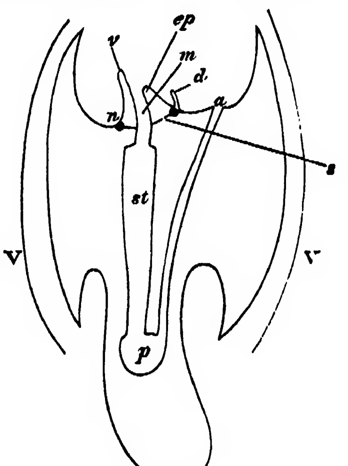

Diagram of body plan of *Brachiopod, Polyzoon,* and *Phoronis* (after Caldwell).—*m*, mouth; *a*, anus; *s*, septum; *n*, nervous system; *st*, stomach; *p*, second stomach; *ep*, epistome; *v*, tentacle of ventral series; *d*, tentacle of dorsal series; V V valves of Brachiopod skull.

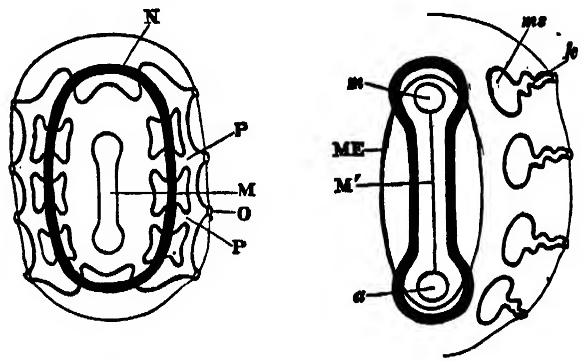
Van Bemmelen, in a recent paper (*Jenaische Zeitschrift*, 1883) has compared at great length the Brachiopods with Sagitta, and arrives at the conclusion that the two types show such intimate agreement that they must be looked upon as very closely related. In the first place Dr. van Bemmelen recounts the histological resemblance between Sagitta and Brachiopods; and if he ascribes more weight to these than his readers may be inclined to do, he is not without weightier considerations in support of them. In both groups connective tissue is conspicuously scanty; in both a homogeneous intercellular substance or mesenchyme-layer is abundant. The epithelial layers are extremely simple and alike in both; the muscles in both are "built on an epithelial type;" the histological characters of the nervous system are identical in both. The chitinous hairs developed in ectodermal follicles on the mantle of Brachiopods are not without analogues in the Chætognatha. The three metameres of the larval Brachiopod are compared with the divisions of the adult Sagitta; the four genital glands of the former (Testicardines) are identified with the ovaries and testes of the latter. The gastro- and ileo-parietal bands of the Brachiopod are made homologous with the transverse septa of Sagitta, and the hood of Sagitta with the arms of the Brachiopod. It is obvious that the above characters, many of which are mentioned in the Hertwig's "Cœlomtheorie," are of very unequal value; and some are even wrong, for the gastro- and ileo-parietal bands of a Brachiopod are parallel with the gut, and in no way comparable to the transverse septa of Sagitta. But, on the other hand, there are other suggestive points of resemblance, and, though further developmental evidence in the case of Sagitta is sorely needed, I think that its possible affinity to the Phoronis type cannot be altogether passed over. Not only is the development of the mesoblast and body-cavity strikingly similar, but the dorsal and ventral mesenteries at first present in Phoronis agree with those of Sagitta, and the septum dividing off a part of the body-cavity within the head seems the same in both. Nothing in the nervous system offers great difficulty, and the relations of the hood in Sagitta seem not discordant with those of a lophophore. If we approximate the anus and mouth dorsally in Sagitta, the "olfactory organ" will assume the position of the two sense-organs of Phoronis and Rhabdopleura. The lateral mesenteries of Phoronis and Brachiopods arise late and secondarily, as does the transverse septum of the trunk in Sagitta. The anterior and posterior generative masses, arising first together, are no sign of true segmentation, and our embryological knowledge of the nephridia of Sagitta is too slight to permit us to make much use of them as arguments on either side.

If all this is true (and I am far from insisting upon it), it means that Sagitta (though extremely modified for a pelagic life) is akin to the unflexed, unsegmented worm, which, as it acquired a dorsal flexure and a more complex lophophore, gave rise to the proximate ancestors of the Phoronis type.



A. B.

Sedgwick's theory of segmentation: A. Ideal ancestor of segmented animals; B. Invertebrate.—M, primitive mouth; *m*, mouth; *a*, anus; M', middle portion of primitive mouth or blastopore closed up; N, nervous system; P, pouch of gut; *ms*, mesoblastic somite; *k*, nephridium; O, external pore; ME, mesenteron.

And if we admit this even for a moment, it becomes worth while to consider the possibility of a distant Molluscan connection with the same line; for, possessing a trochosphere larva, a single pair of nephridia, and a nervous system with no trace of genuine segmentation, they are so far in agreement with our type. I cannot see that Caldwell's discoveries necessarily invalidate Lankester's old comparison of the Lamellibranch gills (and labial palps) with a lophophore; and even Lankester himself, in spite of his opinion already quoted, that, owing to Caldwell's research, Polyzoa, &c., must now be removed from the Molluscan phylum, yet still admits (*loc. cit.* p. 688) that "it is very probable that the labial tentacles and gill-plates are modifications of a double horseshoe-shaped area of ciliated filamentous processes, which existed in ancestral Mollusks much as in Phoronis and the Polyzoa, and is to be compared with the continuous præ- and post-oral ciliated band of the Echinid larva Pluteus, and of Tornaria;" and Langerhans' close comparison between the nervous systems of Sagitta and a Mollusk may be worth more consideration. The molluscan foot may, after all, be an epistome, as Lankester formerly said, and the "osphradia" of the Mollusk may turn out homologous with the sense-organs of Phoronis and Rhabdopleura. But the extreme modifications that the Molluscan type has undergone—the reduction of the body-cavity, the development of the foot, the various flexures, and so forth—leave any connection that we may trace with it and our Sagitta type at best a distant one; if such exists, a distant relationship will be again traceable between Mollusks and

Brachiopods, though every argument on which their former connection was based is demonstrably false.

But to a great extent the whole matter turns upon our conception of *segmentation*, a subject which Mr. Sedgwick's recent speculations (*Q. J. M. S.*, No. xciii. 1884) may very seriously modify. Sedgwick derives all metameric segmentation from a Cœlenterate-like ancestor, with a *pouched gut* like that of all the Actinozoa. The blastopore, including both mouth and anus, is derived from the Actinozoan mouth, the double nerve-cord from the aggregation of the nervous system round the mouth of the polyp, and the nephridia from specialised parts of the pouches represented now by the circular canal of Medusæ or the mesenteric perforations of Actinozoa and the pores leading to the exterior in those forms from the mesenteric chambers. But it is impossible to discuss this theory fully; it is enough to point out that it postulates segmented ancestors of all animals above Cœlenterates. Mollusks, Brachiopods, and Sagitta must according to it have been once segmented, just like Vertebrates, Arthropods, and Worms. But surely this is a violent assumption. There is no evidence of segmentation among Mollusks save in Nautilus, for even the pedal commissures of Chiton in no way indicate a truly segmented condition; nor any among Polyzoa or Brachiopods save the four nephridia of Rhynchonella. And it is by no means clear that the development of Sagitta indicates its descent from an ancestor with "*three pairs* of gut-pouches." The vast number of animals with a single pair of nephridia can scarcely all be derived from ancestors with many pairs; and Hatschek's description of the origin of segmented nephridia (in Polygordius) from a single pair seems far from supporting Sedgwick's view. The still insufficiently investigated excretory organs of Rhynchonella, and the four gills, &c., of Nautilus, seem not enough to indicate descent of the groups to which these forms belong from segmented ancestors. On the contrary, it seems far more likely that the types we have more particularly discussed are all derived from some unsegmented trochosphere; and that the segmentation of the Chætopods only became marked after the ancestor of the Phoronis type had severed his course from the common stock of Worms. The distinction of segmentation and non-segmentation would thus divide the Invertebrata.

As regards the Gephyrea, there is much reason for connecting such members of the group as Sipunculus, Phascolosoma, and Bonellia with the unsegmented Phoronis type. But Hatschek maintains that the development of Echiurus proves it to be a degenerate Chætopod; and if so, Caldwell (*loc. cit.*) is ready to admit that the others may be further stages in such degeneration. But even as regards Echiurus this degeneration is far from clear. The Platyelminths seem also never to have been segmented, and their "water-vascular canals" may give us some indication of the organs from which are derived the nephridia of Phoronis, Gephyrea, Brachiopods, and Mollusks. The larva of Thysanozoon has many points in common with the trochosphere, though its want of an anus is strange and difficult to explain. The Rotifers are acknowledged to be persistent trochospheres. And accordingly all these forms may be older and more primitive, by virtue of their lack of segmentation, than all the Chætopods.

D. W. T.

SCIENTIFIC SERIALS

THE *Journal of Anatomy and Physiology*, January 1884, contains:—A. Milnes Marshall, M.D., certain abnormal conditions of the reproductive organs of the frog.—S. A. Waddell, M.B., the urea elimination under the use of potassium fluoride in health.—B. C. A. Windle, M.A., M.D., primary sarcoma of the kidney.—R. J. Anderson, M.D., transverse measurements of human ribs.—Arthur W. Hare, M.B., a method of determining the position of the fissure of Rolando and some other cerebral fissures in the living subject.—G. Hoggan, M.B., new forms of nerve terminations in mammalian skin.—J. Symington, M.B., the fold of the nates.—W. Ainslie Holles, M.D., researches into the histology of the central gray substance of the spinal cord and medulla oblongata.—D. J. Cunningham, M.D., the musculus sternalis.—C. W. Cathcart, M.B., movements of the shoulder-girdle involved in those of the arm on the trunk.—J. B. Sutton, the relation of the orbito-sphenoid to the region pterion in the side wall of the skull.—Anatomical notices.

April contains:—J. B. Sutton, the nature of certain ligaments.—F. Le Gros Clark, F.R.S., some remarks on nervous exhaustion, and on vasomotor action.—C. B. Lockwood, F.R.C.S. Lond., the development of the great omentum and the transverse mesocolon.—Arthur Thomson, M.B., notes of two instances of abnormality in the course and distribution of the radial artery.—Js. W. Barrett, M.B., the cause of the first sound of the heart, and the mode of action of the cardiac muscle.—Prof. Cleland, F.R.S., notes on raising the arm.—R. W. Shufeldt, M.D., osteology of *Ceryle alcyon*.—A. M. Patterson, M.B., notes on abnormalities, with special reference to the vertebral arteries.—Geo. Hoggan, M.B., on multiple lymphatic nævi of the skin, and their relation to some kindred diseases of the lymphatics.—Prof. Cleland, F.R.S., notes on the viscera of the porpoise and white-beaked dolphin.—W. Arbuthnot Lane, F.R.C.S., costal and sternal asymmetry.—Anatomical notices.

THE *Journal of Physiology*, vol. v. No. 1, contains:—E. Klein, M.D., F.R.S., the bacteria of swine-plague.—T. Lauder Brunton, on the rhythmic contraction of the capillaries in man, and on the physiological action of condurango.—J. Blake, on the connection between physiological action and chemical constitution.—H. H. Donaldson, and L. T. Stevens, note on the action of digitalis.—W. H. Gaskell, on the augmentator (accelerator) nerves of the heart of cold-blooded animals.

Archives Italiennes de Biologie, tome iv. fasc. 3, contains:—B. Grassi, the development of the vertebral column in bony fish.—L. Luciani, on the mechanical stimulation of the sensomotory centres of the brain-cortex.—A. Moriggia, on a new method of isolating the sensibility of the mobility of the nerves.—G. Magini, the induced unipolar current and the stimulation of nerves.—F. Marino-Zuco, upon the ptomaïnes with regard to toxicological investigations.—S. Richiardi, on the distribution of the nerves in the follicle of the tactile hairs of the ox, which are provided with a vascular erectile apparatus.—Ph. Lussana: (1) on the brain of the boa: considerations on comparative neuro-physiology; (2) on the sensibility of parts uncovered by skin; (3) on colour-hearing.—A. Marcacci, the areola-mammillary muscle.—P. Foà, contribution to the study of the physiopathology of the spleen.—L. Griffini and G. Tizzoni, experimental study of the partial reproduction of the spleen; novel researches into the total reproduction of the spleen: an experimental contribution to the hematopoetic function of the connective tissue.—J. Bizzozero and A. A. Torre, upon the origin of red blood-corpuscles in the various orders of the Vertebrata.—J. Cattaneo, fixation, staining, and preservation of Infusoria.

Tome v. fasc. 1 contains:—C. Giacomini, the fascia dentata of the hippocampus major in the human brain.—A. Borzi, new studies in the sexuality of Ascomycetes (preliminary note).—L. Solera, contribution to the physiology of the succus intestinalis.—F. Selmi, tolerance of arsenic in domestic animals, and its distribution in the organism.—Ph. Lussana, on the quantitative and qualitative secretion of bile in the state of inanition after the section of the two pneumo-gastric nerves.—L. Camerano, (1) on the development of the Amphibia, and on what has been called their "Neotenia"; (2) researches on the prolongation of the branchial periods of the Amphibia.—G. Romiti, anatomical investigation of a case of death from the bite of a viper.—P. Fanzago, on the nest of *Geophilus flavus*.—E. Levier, the origin of the tulips of Savoy and of Italy.—P. Albertoni, critical and experimental studies upon the action and metamorphosis of certain substances in the organism, with respect to the pathogenesis of acetonæmia and diabetes.—L. Griffini, (1) an experimental study of the partial regeneration of the liver (preliminary communication); (2) on the total and partial reproduction of the follicular apparatus and of the calyciform papillæ in the rabbit (preliminary communication).—M. H. Peracca and C. Deregibus, note on *Cœlopeltis insignitus*.—L. Vincenzi, histological note on the true origin of some cerebral nerves.—A. Mosso, employment of the balance in the study of the circulation in man.

SOCIETIES AND ACADEMIES

EDINBURGH

Mineralogical Society, June 24.—This meeting was held at the Museum of Science and Art, Edinburgh.—Prof. Jas. Geikie, F.R.S., in the chair.—The following papers were read:—On forms of silica, by Prof. John Ruskin, D.C.L. The Chairman and Dr. Dudgeon made some remarks.—On the application of the periodical law to mineralogy, by Prof. Thos. Carnelley of Dundee.—On the origin of the Andalusite schists of Aberdeenshire, by

Mr. John Horne, F.G.S.—On the occurrence of Prehnite and other zeolites in the rocks of Samson's Ribs and Salisbury Crags, by Mr. Andrew Taylor.—On a new locality for zoisite at Loch Garve, Ross-shire, by Mr. Hamilton-Bell.—On diatomaceous deposits in Scotland, by Prof. W. Ivison Macadam. The author drew attention to the vast extent of some of these beds, and gave particulars as to the proportions of silica, &c., contained in them. The deposits were being worked up to yield an absorbent for dynamite manufacture, and gave a material having double the liquid retaining power of samples of "kieselguhr" experimented on.—On the albertite beds of Strathpeffer, Ross-shire, by Mr. Wm. Morrison. Mr. J. Stuart Thomson referred to the fact that an allied jet mineral was found embedded in the oil-yielding bituminous shales of Midlothian. The substance only occurred in small quantities, the largest pieces not exceeding a pound in weight. It is capable of taking a fine polish, being similar to jet. In fact a jet-worker pronounced it at first to be Spanish jet.—On new localities for kyanite in Glen Urquhart, Drumlach Glen, Inverness-shire, and for staurolite at Presholme, Enzie, Banffshire, by Mr. Thomas Walker.—On the crystallography of Bournonite, by Mr. H. R. Miers, British Museum. The paper criticised the history of the subject, and corrected various errors which have crept into the earlier literature. To those crystallographic forms hitherto recorded twenty-nine new forms are added as determined without doubt, and twenty-one as probable. A list of over 1000 angles, calculated from the elements of Miller, is given. The twinning (twin-plate the prism 110) is discussed; the observations of Hessenberg are supported, and it is concluded that the twinning is always by juxtaposition, not by interpenetration, but that Cornish crystals afford an example of composition perpendicular to, as well as parallel to, the plane of composition.—On a peculiar development of tourmaline from Lockport, New York County, by Mr. R. H. Solly, F.G.S.—Notes on the metallic veins of the Upper Hartz, Germany, by Mr. H. M. Cadell.—Scottish localities for actinolites, by Mr. Peyton.—On Welsh gold, by Mr. T. A. Readwin. A specimen weighing 160 grains, from the Mawddach Valley, Merionethshire, was exhibited.

DUBLIN

Royal Society, June 16.—Section of Physical and Experimental Science.—G. Johnstone Stoney, D.Sc., F.R.S., Vice-President, in the chair.—The following papers were read by Prof. G. F. Fitzgerald, M.A., F.R.S., Hon. Sec.:—(1) On a non-sparking dynamo. By applying the principles of Maxwell's modification of Thomson's electrical doubler to a dynamo in which the current passes through two or more coils in parallel circuit, it is possible to arrange the magnetic field and the brushes so that when the terminals of any coil come into contact with their brushes, the terminals shall be at the same difference of potential as the brushes, and that when they break contact there shall be no current running in the coil, thus avoiding all sparking. The energy of self-induction usually wasted on local currents and sparks will in this case be spent in producing useful current.—(2) On dust repulsion. Prof. Osborne Reynolds's theory of the action of the radiometer leads to the conclusion that a very small body in dense gas is subject to similar forces as the vanes of a radiometer in rare gas, and he made experiments which showed that silk fibres in air at considerable pressures were subject to apparent repulsion by radiation: a similar action on dust would explain the dust repulsion observed by Dr. Lodge.—(3) On currents of gas on the vortex atom theory of gases. As the momentum of a simple ring vortex is not proportional to its velocity and varies with its temperature, the momentum of a current of vortex rings would do so too. This and the variations with temperature of the velocity of sound and of the diffusion of gas through small apertures all point to the conclusion that a simple vortex ring is certainly too simple to explain the laws of material atoms. A difficulty is raised as to the amount by which the medium is carried forward by the translation and rotation of the earth.—(4) On a method of studying transient currents by means of an electrodynamometer. By comparing the initial swing of a ballistic galvanometer which depends on $S\,C\,dt$ with the initial swing of an electrodynamometer which depends on $S\,C^2\,dt$ it is possible in many cases to determine, in addition to the total quantity of electricity that passes in the current, several matters as to the distribution of the current during its time of passage.—Prof. E. Hull, LL.D., F.R.S., on the geological age of the North Atlantic Ocean as bearing on the question of the permanency of continents and oceans. After referring to the views of those who hold the doctrine of "the permanency of oceans and continents" as opposed to those who, with Lyell, hold that continents and oceans have been interchanged during the past history of the globe, the author proceeded to consider how the formation of the North Atlantic Ocean might be adduced in support of one or other of these views. Remarking that this ocean was the only one at present known which could be used in evidence, inasmuch as we were in possession of sufficient knowledge of the geological structure of the regions by which it is bounded to the east and to the west, he proceeded to show how the distribution of the Silurian and Carboniferous rocks of North America, on the one hand, and of the British Isles and Western Europe on the other, pointed to the existence of the derivative lands in the direction of the Atlantic Ocean during these periods. In each case it was shown, by reference to details, that the sedimentary portions of these formations swell out towards the borders of the ocean, and tail out or become attenuated towards the interior of the continents in the opposite directions. From this it was inferred that the lands from which the sediment was derived occupied the region now overspread by the ocean; and, considering the great thickness of the sediments of these formations, the derivative lands were inferred to be of continental proportions. An additional argument in support of this view was also adduced from the distribution of the calcareous with the sedimentary deposits; for it was shown that the calcareous deposits (which were in the main of marine organic origin) swell out and sometimes replace the sedimentary deposits, as we recede from the borders of the ocean on either hand. From these considerations the author concluded that down to the close of the Carboniferous period the North Atlantic was for the most part in the condition of a continent, while the regions of Central and Eastern America, and of the British Isles and Western Europe, were submerged under oceanic waters. After this period, however, the relations were altered. With the upheaval of the Alleghanies at the close of the Palæozoic epoch, and with the terrestrial movement which at the same time affected the Carboniferous and older rocks of the British Islands and Western Europe, the Atlantic continent was converted into an ocean, in which condition it has remained to a great degree ever since. The author inferred from all this that the history of the North Atlantic Ocean might be adduced in support of the views of those who hold the doctrine of the "interchangeability of oceans and continents" rather than of the other.

Section of Natural Science.—Rev. M. H. Close, M.A., in the chair.—Rev. Dr. Haughton, F.R.S., on the possibility of the formation of coloured solar and lunar halos produced by the suspension in the air of volcanic dust caused by the explosion of Krakatoa in August 1883.—Prof. C. R. C. Tichborne, Ph.D., on an argentiferous galenitic blende found at Ovoca, Co. Wicklow. This mineral is very little known; it has been called "kilmacooite" locally in Ovoca, and it is generally termed "blue-stone" in the Island of Anglesey, the only two places in the United Kingdom where it is found. An analysis of the mineral made by the author gave the following results:—

Silver[1]	0·024
Zinc	25·27
Lead	25·18
Iron	5·51
Manganese	trace
Antimony	0·21
Arsenic	0·08
Copper	2·50
Alumina	0·60
Magnesia, with traces of Calcium	0·02
Sulphur	23·71
Silica	16·896
	100·000

This mineral contains various amounts of pyrites according to the situation of the lode. The specific gravity was 4·73—intermediate between blende and galena—but it was harder than either of these minerals, and was therefore raised by blasting. The author finds by experiments that this mineral is a mechanical

[1] Equal to about 8 troy ounces per ton, or 8¾ ounces avoirdupois. The mineral may be said therefore to consist of—

Sulphide of zinc	37·68 per cent.
Sulphide of lead	29·07 ,,
Sulphide of silver	0·0275 ,,

mixture of microscopic crystals of blende and galena ; it forms a fine-grained saccharoidal mass, very homogeneous in structure, except as regards the pyrites, and occurs in isolated crystals easily discernible by the eye. The author objected to the terms which had been applied to this mineral on the grounds that they were too local, and did not describe the ore. He explained his method of determining the actual physical as well as the chemical composition of the ore. In conclusion, he said that he was tempted to quote from his report upon the Dublin International Exhibition of 1865 in connection with the raising of silver in Ireland. At that time he found that this country was a large supplier of silver, but he was almost afraid to make the calculation now that he then made of the silver supplied by Ireland. He stated that in 1865 Ireland yielded 14,000 ounces of silver per annum, or 2·4 per cent. of the whole of the silver raised in the world, and its value might be estimated at 3850*l*. per annum, exclusive of the accompanying lead. If 1000 tons of this ore could be supplied, which represented of silver alone 8000 ounces, how lamentable it seemed that this valuable industrial resource should remain unworked.—G. H. Kinahan, M.R.I.A., notes on the earthquake that took place in Essex on the morning of April 22, 1884.

SYDNEY

Royal Society of New South Wales, June 4.—H. C. Russell, B.A., F.R.A.S., President, in the chair.—Three new members were elected, and forty-six donations were received.—The following papers were read:—On rain and its causes, by Edwin Lowe, in which he advocated the firing of cannon and of explosives for bringing about the precipitation of rain.—On the removal of bars from the entrances to our rivers, by Walter Shellshear, Assoc.M.Inst.C.E.—A specimen of scum from a pond near Campbelltown was exhibited. It had been noticed that the surface of the water was covered with a rich green growth in the mornings, and that this changed to a deep red in the afternoons. Messrs. Morris, M.R.C.S., and Wright, M.R.C.S., stated that it appeared to be due to *Astasia hæmatodes*, Ehr.

PARIS

Academy of Sciences, July 21.—M. Rolland, President, in the chair.—Presentation of two unpublished essays of Augustin Fresnel, found among the papers of Ampère, by M. Bertrand. The subjects of these essays are the following:—(1) Comparison of the hypothesis of electric currents round the axis of a magnet with that of electric currents round each molecule of matter; (2) Second note on the hypothesis of particular electric currents. These documents are both in the handwriting of Fresnel, but without title or signature, and one only bears a date, that of June 5, 1821.—A study of the geometrical deformations determined by the crushing of a straight cylinder in the direction of its axis between two planes (two illustrations), by M. Tresca.—On two theorems of Prof. Sylvester in connection with his complete demonstration of the rule of Newton in the form given to it by Newton himself, by M. de Jonquières.—Note on the equation in matrices $px = xq$ (continued), by Prof. Sylvester.—On the solution of the most general case of linear equations in binary quantities, that is to say, in quaternions or in matrices of the second order, by Prof. Sylvester.—Note on the maritime canals of Suez and Panama, by M. de Lesseps. In presenting the report of the International Commission on the widening of the Suez Canal, the author expresses the hope that it will soon be able to afford easy passage to ten or twelve million tons of shipping yearly. The Panama Canal, he expects on the report of Mr. Dingler, will be completed in the year 1888.—On the proposed formation of a so-called inland sea in Algeria and Tunisia, by M. E. Cosson. The author repeats the objections already urged against M. Roudaire's project, which, in the discussion that ensued, was supported by M. de Lesseps.—Remarks in connection with the last letter received from Lapérouse, dated Botany Bay, February 7, 1788, by M. de Jonquières.—On electro-capillary relations, by M. P. Garbe.—Direct measure of the two static components and of the dynamic component of the magnetic field of condensing-machines, by M. G. Cabanellas.—Researches on magnetism, by M. Duter.—On a new electric pile with carbon electrodes, producing an electromotor force equal to 0·6 volt, by MM. D. Tommasi and Radiguet.—On the numerical value of Poisson's coefficient as determined by experiments made with caoutchouc, by M. E. H. Amagat.—Temperature and critical pressure of nitrogen; boiling points of nitrogen and ethylene under slight pressures, by M. K. Olszewski.—On the properties of the liquefied vapour of ethylene, and on its employment as a refrigerator, by M. S. Wroblewski.—Action of the induction spark on benzine, toluene, and aniline, by M. A. Destrem.—On the production of a crystallised manganite of baryta, by MM. G. Rousseau and A. Saglier.—On the combinations formed by the sesquichloride of chromium with the other metallic chlorides, by M. L. Godefroy.—On a general reaction of the polyatomic alcohols in presence of borax, and of the paratungstates, by M. D. Klein.—Remarks on the disinfecting properties of borax applied inwardly, by M. E. de Cyon. From experiments continued over six years the author concludes that borax is a powerful antiseptic, and that it may be introduced in any required quantity into the system to preserve it from all contagions caused by parasites or microbes. As a prophylactic against cholera he recommends boric acid or a solution of borax to be applied to all the external mucous membranes, and about six grains of borax to be taken every twenty-four hours with the food and drink. It appears not only to act directly on the microbes contained in the intestinal canal, but also to attack the bacilli that may have penetrated into the blood.—Researches on the physiological development of *Cerocoma schreberi*, *Stenoria apicalis*, and other insects of the order of Cantharides, by M. H. Beauregard.—Remarks on the action of the heart in insects during their metamorphosis, by M. J. Künckel.—Note on the origin and distribution of phosphorus in coal and cannel-coal, by M. A. Carnot.—On the variation, under pressure, of the temperature determining the transformation of the iodide of silver, by MM. Mallard and Le Chatelier.—Researches on the influence of light on the respiration of vegetable tissues destitute of chlorophyll, by MM. G. Bonnier and L. Mangin.

VIENNA

Imperial Academy of Sciences, June 13.—E. Mach and T. Wentzel, on the fixation of a very transitory phenomenon by instantaneous photography.—E. Tangl, on the continuity of protoplasm in vegetable tissue.—M. Loewit, contributions to theory of blood-coagulation, ii., on the importance of the blood-disks.—B. Schudel, on propylidene-dipropyl-ether.

THURSDAY, AUGUST 7, 1884

ELECTRIC LIGHTING

A Practical Treatise on Electric Lighting. By J. E. H. Gordon. (London: Sampson Low and Co., 1884.)

PRACTICAL treatises on this subject are very numerous, but they do not emanate from the right men. We want a book from a perfectly independent authority, unflavoured with the taint of invention, the result of practical experience. Mr. Gordon is in many respects well qualified for the task, but he is an inventor, and his book is strongly impregnated with prejudice and a green-spectacle view of the subject. He is, however, a staunch believer in the immediate future of successful electric lighting, and is very hopeful that the dark clouds that now envelop it will be dispelled by the enlightenment of steady progress.

After an introductory chapter on the general principles of artificial lighting, he deals with the conversion of electric currents into heat, and shows how carbon, when raised to incandescence, fulfils all the conditions required to give the maximum light with the minimum expenditure of heat. The problem is to concentrate the heat in a solid of the smallest possible size or with the smallest possible cooling surface. Electrical units—amperes, volts, ohms, coulombs—and their relation to each other and to the ordinary heat and work units are explained, though, curiously enough, that most useful and much employed unit the *watt* is not even mentioned. The rules that regulate derived currents lead to an investigation of the method of calculating the power wasted in a network of conductors—a matter of very serious consequence in the commercial aspect of electric lighting, though Mr. Gordon does not touch on any of the recent methods devised to reduce the excessive cost of mains. We then have a disquisition on the experimental measurements of currents, electromotive forces, resistances, and power developed, with a description of various indicators and measurers employed. No reliable instrument has yet been introduced for ordinary practical use, and there are many instruments now undergoing trial which Mr. Gordon has not touched upon—particularly those of Marcel Deprez in use on the Continent, and which were exhibited at Munich and Vienna.

A capital chapter is devoted to glow lamps. "The first public exhibition of incandescent lamps that was made in this country was made by Mr. Swan before the Society of Telegraph Engineers on November 24, 1880. The first exhibition in America was made by Mr. Edison" (p. 62). Mr. Gordon does not give the date! Arc lamps follow, Mr. Crompton's admirable lamp being that selected for description.

Perhaps the most valuable and certainly the most novel chapter in the book is that written by Mr. Crompton on carbons used in arc lamps. The following information is useful (p. 105):—

"The diameters most commonly used have been as follows:

For currents from	7–12 amperes	9 mm. to 11 mm. diameter.
,,	12–18 ,,	11 mm. to 13 mm. ,,
,,	18–25 ,,	13 mm. to 15 mm. ,,
,,	25–40 ,,	15 mm. to 18 mm. ,,
,,	40 upwards	18 mm. to 20 mm. ,, "

And the following is startling:—

Illuminating Power per Electrical H.P. of 13 mm. Carbons of different Makers. Currents from 15 to 20 amperes

Name of Maker	Candle Power per H.P.
Siemens (cored), pos. } Carré (cored), neg. }	4270
Siemens (cored)	3514
Barnsley Co.	3500
Johnson and Phillips	2986
Sautter and Lemonnier	2920
Carré (not cored)	2773
Silvertown (Gray's)	2580
Carré (cored)	1972

We then have a chapter on magnets and electro-magnetic induction, which leads to the general principles and theory of electric generators, including a very admirable account of that important subject, self-induction.

"*It is found experimentally, and can be proved mathematically, that if a coil of wire forms part of a circuit, and an alternating E.M.F. sends a current through it, that the current will be much less than it would have been had the same resistance been interposed in the form of a straight wire.*

"*Further, the proportional diminution becomes greater as the current is increased by the reduction of the resistance; and finally, for a given E.M.F., a given rate of alternation, and a coil of given shape, a limit is reached beyond which even reducing the resistance to zero does not increase the current*" (p. 123).

"*This diminution, however, does not, to the best of my belief, waste energy or diminish the efficiency of the machine; it only diminishes its output. Thus self-induction increases the size of a machine required to feed a certain number of lamps, but it does not perceptibly increase the H.P. required to drive the machine with that number of lamps on it.*

"The effect of self-induction increases as the current increases, and therefore *short-circuiting a coil of an alternating machine does not indefinitely increase the current in that coil, and seldom increases it enough to injure the insulation*" (p. 137).[1]

Of course we have a good description of alternate-current machines, and after some adverse criticism of the Ferranti type (which is imperfectly described), and not justified by the performance of the latter, Mr. Gordon describes his own form, which is chiefly distinguished by its size and weight. A few direct-current machines are described—not the best—and their regulation briefly referred to, with the curious conclusion (p. 183):—

"CONCLUSION.

"*The true secret of successful regulation is to have very large dynamos, because then, as we have said before, the maximum number of lamps that can be turned out at one time is a very small percentage of the whole*, and when there are a great number of lamps on one machine, the cost per lamp of regulating, either by hand or by an elaborate mechanical contrivance, is very trifling."

Goulard and Gibbs' secondary generators and the various secondary batteries are briefly despatched. *Apropos* of the latter he says (p. 191):—

"*There is no doubt that the interest and depreciation on a set of secondary batteries large enough to enable an electric light plant to work day and night, and so give*

[1] The italics are not ours.

out to the lamps no electricity in the day but a double quantity in the night, is vastly greater than the interest and depreciation on a complete duplicate set of engines, boilers, and dynamos."

Photometry has only one page devoted to it, and Chapter XIX. is so unique that we reproduce it in full (p. 201):-

"CHAPTER XIX

"CENTRAL STATION LIGHTING

"I had intended to write a long chapter with the above heading, but, for various reasons, I am not yet prepared to do so. I have, however, left in the heading, for the convenience of inserting such a chapter in a future edition of this book, should one ever be required."

This reminds one of the celebrated chapter about Snakes in Ireland: "There are no snakes in Ireland."

The book ends with the excellent rules and regulations for the prevention of fire risks prepared by the Society of Telegraph Engineers. Several useful tables are given in the appendix.

The book is disappointing not for what it contains but for what it does not contain. There is in it a strange mixture of the elementary and the advanced. After an algebraical description of the relations that exist between current work and power, we are told by a footnote (p. 19), "The symbol √ means 'square root of' the quantity under it." There is much hasty editing. At p. 30 we are promised in a footnote a mathematical proof in the appendix which does not appear there. At p. 25 the symbol for a battery is wrong - the poles are reversed. The present value of H at Greenwich is given at p. 40 as ·1794, and at p. 48 as ·181. The illustrations, it may be remarked, are excellent.

It is to be hoped that a second edition will soon be required, so that Mr. Gordon may be able to remedy the defects of the present one. A good practical treatise is very much needed. W. H. P.

OUR BOOK SHELF

A Text-Book on the Method of Least Squares. By Mansfield Merriman. (New York: John Wiley and Sons, 1884.)

THIS may almost be looked upon as a second edition of the "Elements" by the same author, which we favourably noticed in NATURE (vol. xviii. p. 299) soon after its appearance. The sale of the entire edition of the smaller book may be taken as evidence of its having met a want. The present work, though larger in appearance, covers about the same extent of ground, but, as is pointed out by the author, "the alterations and additions have been so numerous and radical as to render this a new and distinct book rather than a second edition."

In Chapters I. to IV., which present the mathematical developments of the principles, methods, and formulas, Dr. Merriman gives an introduction, and discusses the law of probability of error, the adjustment of observations, and the precision of observations at some length, and illustrates with numerous (for this subject) examples. In Chapters V. to IX. the application of the above to different classes of observations is made. These chapters are respectively headed: Direct Observations on a Single Quantity, Functions of Observed Quantities, Independent Observations on Several Quantities, Conditioned Observations, and the Discussion of Observations. These discussions are likely to be of use to engineers and others specially interested in this branch of mathematics. In an appendix, *inter alia*, there is a short statistical statement on the history and literature of the subject, but the fuller list of literature of the earlier book is not reproduced: there are also given here eight handy tables and some other useful material. It is the only work of the kind with which we are acquainted, and is even better adapted, in our opinion, for the end Dr. Merriman has in view than his earlier book was.

Some Propositions in Geometry. In Five Parts. By John Harris. (London: Wertheimer, Lea, and Co., 1884.)

WHEN we received the parcel containing this work with some others for review, we speculated upon what the Editor could have sent us, and hope rose within our breast that some *magnum opus* awaited our perusal. But as we had heard no whisper of such work being on its way, our expectation cooled, and again casting our eyes on the unopened packet, and remembering former works of similar dimensions, a chill seized us, and we thought to ourselves, "Aut H. aut..." Shade of De Morgan! what are we to do with a work occupying 144 + 8 quarto pages treating of a subject so thoroughly threshed out, we had hoped, in your immortal "Budget"?

The title is an attractive one, and much of the work appears to be sound, but when we come across such problems as the trisection of any angle, the inscription of heptagons and nonagons in circles, *et id genus omne*, one draws in one's breath, and one's hair stands on end! The tentative methods given we dare say would enable one to perform these several operations to a very close degree of approximation, but this is not what ordinary mathematicians want. But we must be careful here, for Mr. Harris puts the question, "What is a *mathematician?*" and in his answer splits the creature up into "sorts." There is, for instance, the very positive and readily incensed mathematician, the highly exalted mathematician, the profound mathematician, and the exclusive orthodox mathematician.

It is under this last "sort" that we fear we must be classed. With him "'Mathematics' is a sort of privileged religion, having its special *articles* and technical dogmas. None but the initiated must enter its temple, and woe be to him who dares to do so without a formal certificate from its priests. One of his most valued dogmas is that $\pi = 3{\cdot}14159\ldots$ This is called an approximation; and which if a man do not faithfully believe he will inevitably go—— Ah, well, never mind where he will go to; but, at all events, no mathematician must hold converse or communication with such a profane person."

It will be seen from this extract that Mr. Harris is a man of some humour, but even such oases do not render the vast Sahara of much of his book pleasanter reading. Indeed we have found it very hard work, and so we contented ourselves (for review purposes) with the careful reading of one of the "trisection" proofs; but we gave up in despair, as this proof involved the mastery of a previous proof, and we feared it would be a case of little fleas and lesser fleas, "and so *ad infinitum*." What did we do next? Why we applied a trigonometrical test, and found that the method in the text would not give the result at all, except in a special case. Life is really too short for such verification, and we must leave the task to others. The figures, as usual with Mr. Harris, are carefully drawn and very elaborate diagrams.

We regret more and more that so much labour should be bestowed upon such studies, which, we fear, an unbelieving world will never take up. What, then, is the value of π? It is here said to be (Mr. Harris would say, proved to be) equal to $\sqrt{8} \times \frac{10}{9} = 3{\cdot}142696\ldots$

We lay down the book more in sorrow and pity than in anger and scorn.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

"Gas-Burners, Old and New"

PERMIT me to point out a very obvious clerical error in the notice, in last week's NATURE (p. 270) of my little work having the above title, and to make a few remarks concerning your criticisms on the book. In the sentence, "'Owen Merriman' has taken pains to insist on the two great *desiderata* of gas-burners—high temperature and low temperature," the latter word is doubtless intended for *pressure;* and the sentence should read "high temperature and low pressure." It would have been scarcely necessary to make this correction, but that the notice may perhaps be read by many who are incapable of suggesting the correct reading, and to whom therefore the sentence as it stands will be absolutely meaningless.

While fully appreciating the kindly nature and intent of your criticisms, I cannot pass by, without a word of defence, your statement that you think I have "gone too far in attempting to give a popular theory of luminous combustion." I hope to be able to show that the particular extracts from that portion of the book to which exception is taken are practically correct, and, so far as could be looked for in a work addressed to miscellaneous readers, sufficiently precise. To this end I will deal with the various extracts *seriatim.* That "the various gases which constitute ordinary coal-gas do not all burn together in the flame" is a matter I had thought to be established beyond reach of dispute. But if evidence is required of the truth of the assertion, I need only point to a table prepared by Prof. Landolt, showing the composition of gases in the different parts of a gas flame, which is given by Prof. T. E. Thorpe, F.R.S., in a lecture on "Flame," forming one of the Manchester series of Science Lectures (Manchester: John Heywood). By this table it is clearly shown that in a gas flame, 3½ inches high, the olefines, or heavy hydrocarbons, do not diminish in amount until a height of 1·58 inches is reached; while the proportion of hydrogen is considerably diminished at a height only of 0·39 inch. Although it may not be mathematically correct to say that "the amount of light developed by any coal-gas flame is *directly proportional* to the degree of intensity to which the temperature of the carbon particles is raised," seeing that the light emitted is not in *exact* proportion to the temperature of heat, the statement is sufficiently correct for a popular treatise. What was chiefly intended to be enforced was that the amount of light evolved from a gas flame increases with its temperature, and in such a work a mathematical degree of exactitude is hardly looked for. Now, with regard to the other matters which are raised. To account for the destruction of luminosity which occurs when air is introduced into a gas flame, two theories have been put forward. According to the first, the heavy hydrocarbons at once meet with sufficient oxygen and are immediately consumed, without their carbon being first raised to a white-hot state; but this theory alone will scarcely explain the phenomenon, seeing that the effect of pure oxygen is to increase the luminosity of a flame. The other and more rational theory—and the one which is more generally accepted—supposes that the inert nitrogen which is thereby introduced reduces the heat-intensity of the flame "below the temperature required to decompose the hydrocarbons." It may be that to some extent both causes are at work. Lastly, as to the relative temperatures of a luminous and a non-luminous flame. Although the *average* temperature of the latter is higher than the former—as indeed it must be, seeing that the same *quantity* of heat is contained in a less space, the non-luminous flame nowhere develops so high a temperature as is found at certain of the hottest portions of the luminous flame. Mr. R. H. Patterson, in an article on the action of the blowpipe considered with reference to the principles of gas illumination (*Journal of Gas Lighting*, &c., vol. xxxv. p. 831), states that in the luminous region of an ordinary gas flame he has succeeded in melting a platinum wire: a result which he could never attain with a non-luminous flame."

July 21 "OWEN MERRIMAN"

[We thank our correspondent for pointing out the clerical error "low temperature" for "low pressure" in our article. We consider that the sentence, "The various simple gases which constitute ordinary coal do not all burn together in the flame; the temperature required to effect their ignition being lower for some of them than for others," is misleading. The ordinary reader would understand this to mean that the constituent having the lowest ignition point catches fire and burns away first, and then the constituent of next lowest ignition point catches fire and burns away, and so on; whereas Blochmann's researches show that the combustions are not distinct, but that the *rate* of combustion of the hydrogen is greater than the rate of combustion of the other inflammable gases.

We do not think it "sufficiently correct" to say that the intensity of light is *directly proportional* to the temperature of the coal-gas flame: perhaps it would be nearer the mark to say that the intensity of the light varies as the fifth power of the temperature within certain limits. The admission of air into the Bunsen flame destroys the luminosity more by *dilution* and *oxidation* than by *refrigeration.*—ED.]

The "Cotton-Spinner"

IN a note on this rare British Holothurian (published in NATURE on June 12, p. 146), I drew a distinction between the kind of observations that were possible to a student in a museum and to one who was working at a laboratory specially adapted for biological investigation and situated on the sea-shore.

The experiences of the last few days have shown me only too well that this distinction was not overdrawn or too refined. By the kindness of Mr. John Snell of Truro, I have been favoured with two consignments of the "Cotton-Spinner;" three specimens which reached me on Monday by parcels post gave very sufficient evidence of having died some hours before. This mishap induced me to propose to Mr. Snell that he should send me specimens by express, and entrust them to the charge of the guard of the train; for this suggestion I am indebted to Dr. Günther. Mr. Snell not only did this to-day, but he was good enough also to warn me by telegram that the specimens would reach Paddington at 8 p.m. this evening. I was at the station to meet them, and I have no doubt that the comparatively fresh condition of the sea water was due to the attention of the guard of the train. Notwithstanding all this care and trouble, the three "Cotton-Spinners" were dead.

I have given this detailed, and, I fear, tedious exposition of the whole case, because it seems to me to clench the argument that the problems of the physiology of marine forms, and especially of those less-known creatures which live at a depth of—like the "Cotton-Spinner"—ten to twenty fathoms, are not soluble at some distance from the coast, however great be the trouble or the care that is taken in forwarding them. We must have a laboratory on the sea-shore.

The only fact that I have been able to observe is that the threads of the "Cotton-Spinner" do undoubtedly attach themselves to objects in their vicinity: one of the specimens obtained this evening was attached to sea-weed; from the cloacal orifice a connected strand of threads, about one-fifth of an inch in width and an inch in length, spread out at its free end into a number of more free threads which had attached themselves to the seaweed which had been placed in the water; they extended over about two inches in breadth. From what I have learnt of the extensile and swelling power of these threads, I should take it that about as much had been expelled as would occupy the greater part of the cloacal cavity. A woodcut illustrating the cloacal cavity so filled by tubes, and drawn from a spirit specimen preserved in the British Museum, will be given in my paper on this animal, which will be published in the next (October) part of the *Proceedings* of the Zoological Society.

August 1 F. JEFFERY BELL

Krakatoa

I MOST respectfully beg to point out to you a few errors made in the English version of my "Short Report on the Krakatoa Eruption," published in NATURE, May 1.

It says on p. 15:—"In this eruption very curious objects were ejected, *i.e.* very smooth, round balls, resembling marbles, to the size of 1½ to 6 centimetres in diameter. *They are full of acids;* they contain 55 per cent. carbonate of lime," &c.

The words italicised are wrong. The original says: *Zij Cruisen sterk met Zuren,* which means: *"they strongly effervesce when*

moistened by powerful acids. P. 11, column 1, line 34, "1860" should be "1680"; p. 12, column 2, line 28, and also p. 13, column 1, line 5, *steatite* should be *pitchstone* (a vitreous variation of pyroxene andesite).

R. D. M. VERBECK,
Director of Java Geological Survey

Buitenzorg, Java, June 19

THE METEOROLOGY OF BEN NEVIS

As regards changes of weather and many other problems of meteorology, a knowledge of the vertical variations which take place in the atmospherical conditions is of first importance; and the only way we can hope to arrive at this knowledge is by regular observations made at stations as near each other as possible in horizontal direction, but differing as much as possible in height. This point was very clearly seen many years ago by the late Mr. Allan Broun, and the idea was practically worked out by him in the elaborate series of meteorological and magnetical observations simultaneously made on the peaks and ridges and in the adjoining valleys of the Western Ghats. These observations are the best anywhere yet made to supply the observational data for the discussion of some of the more important problems of meteorology; and the science sustained no ordinary loss in the death of Mr. Broun before he had discussed the observations which had been collected by his genius, energy, and self-denial.

Next in scientific value to Mr. Broun's observations are those made on Ben Nevis since June 1881. The special advantages of Ben Nevis as a meteorological observatory are that it rises to a height of 4406 feet, and is little more than four miles distant from the sea at Fort William, and that it is situated in the track of the great storms which sweep over North-Western Europe from the Atlantic. Hence observations made on the top and at the base of Ben Nevis possess a value altogether unique in meteorology; particularly in discussing the atmospheric movements which accompany cyclones and anticyclones, and in investigating tornadoes and other destructive winds which originate when the air is abnormally warm and moist near the surface, while aloft the temperature and humidity diminish with abnormal rapidity.

For the preliminary inquiry which is necessary in order to determine the chief points in the meteorology of Ben Nevis, there are now available for a comparison of the climate of the top of the mountain with that of the sea-level at Fort William, simultaneous observations for twenty-two months, viz.: from June to October of the years 1881 and 1882, and from June 1883 to June 1884. As regards the temperature, the monthly means for Fort William were compared with the normal monthly temperatures of that place as given in the paper on the "Climate of the British Islands" (*Journ. Scott. Met. Soc.*, vol. vi. p. 33). From the differences thus obtained, the approximate normal temperatures at Ben Nevis Observatory were determined. The coldest month is February, the mean being $22^{\circ}\cdot0$, and the warmest, July, $41^{\circ}\cdot3$, August being nearly as warm, the mean being $41^{\circ}\cdot1$; and the annual mean temperature $30^{\circ}\cdot9$. Comparing the normals with those of Fort William, the greatest difference is $18^{\circ}\cdot0$ in May, from which it steadily diminishes to $14^{\circ}\cdot9$ in December, and then rises more rapidly to the maximum in May; the annual difference is $16^{\circ}\cdot3$. The greatest difference, or the most rapid fall of temperature with height, is in the spring and early summer, when the climate of the west is driest, the temperature of the Atlantic lowest relatively to that of the air, and the top of the mountain still covered with snow. The least difference is in late autumn and early winter, when the climate of the west is wettest, Ben Nevis most frequently and densely clouded, and the temperature of the Atlantic highest relatively to that of the air. The observations of temperature at the high- and low-level stations show a variation with the hour of the day even more decidedly marked than that with season. Thus, in January the decrease of temperature, deduced from the mean maxima and minima respectively were $16^{\circ}\cdot2$ and $15^{\circ}\cdot2$, but in April these were $23^{\circ}\cdot1$ and $12^{\circ}\cdot9$, being thus in January nearly equal, whereas in April the difference of the maxima was nearly double that of the minima.

The annual means give, therefore, a decrease of temperature with height at the rate of 1° for every 270 feet of ascent—the most rapid decrease being 1° for every 245 feet in April, and the least rapid 296 feet in December.

But the individual observations show wide divergences from these rates of decrease. As disturbing conditions, the more important of these are the instances of abnormally large decrease, seeing that these imply a temperature near the surface much above the normal with respect to the higher strata, by which the equilibrium of the atmosphere is destroyed, and rapidly ascending and descending currents are generated, thus giving rise to some of the most destructive storms of wind. Of the illustrations the observations give of a rapid decrease, reference may be made to those of October 13, the day preceding the great storm which proved so destructive to the fishermen on the Berwickshire coast.

Even more striking, and, as regards their bearing on the theory of storms and weather changes, perhaps even more important, are those instances of abnormally small differences between the temperature at the top and base of the mountain, of which a good example which occurred on September 21, 1882, was given in NATURE, vol. xxvii. p. 176. All such cases have been accompanied with a high temperature and an excessive dryness of the air. It is these qualities of air which immediately connect the phenomena with the great cyclonic and anticyclonic systems in which or near to which Ben Nevis is for the time situated. The most striking case of all occurred on December 31, 1883, on which day the maximum temperature at Fort William was $30^{\circ}\cdot6$, and minimum $27^{\circ}\cdot2$, these being at Ben Nevis Observatory $32^{\circ}\cdot0$ and $22^{\circ}\cdot8$. At 11 a.m. the temperature at Fort William was $27^{\circ}\cdot5$, but on Ben Nevis it was $32^{\circ}\cdot0$, with a wet bulb as low as $24^{\circ}\cdot4$. Hence at this hour the temperature of the air was $4^{\circ}\cdot5$ higher at the Ben Nevis Observatory than at Fort William, 4406 feet lower down, and this relatively high temperature was accompanied with excessive dryness represented by the humidity of 33. From 6 a.m. to noon temperature was continuously higher on Ben Nevis than at Fort William. At 11 a.m. the abnormality in the vertical distribution of the temperature amounted to $20^{\circ}\cdot5$. It is of importance to note that at this time of relatively high temperature and great drought, atmospheric pressure was very high at the Observatory, the reading of the barometer at 32° being 25·915 inches, being absolutely the highest that has occurred from November 28, 1883, to June 30, 1884. At Fort William the sea-level pressure was 30·608 inches.

Another peculiarity of the temperature is the small diurnal variation caused by the sun at all seasons, but particularly in winter; and the large variation due to the temperature changes which accompany the passage of cyclones and anticyclones over the Observatory. The means of the hourly observations show that even in May the difference between the mean warmest and mean coldest hour was only $3^{\circ}\cdot3$. In January the difference was only $0^{\circ}\cdot8$, and in this month the highest hourly mean occurred during the night, and the lowest during the day. On the other hand, the difference of the mean daily maxima and minima for January was $6^{\circ}\cdot7$. In truth, the influence of the sun on the temperature of the air is all but eliminated during the winter months owing to the thick covering of mist, fog, and cloud, in which the mountain is almost constantly wrapped.

Since June 1881 the highest temperature on Ben Nevis was $59^{\circ}\cdot3$ on August 8, 1882, and the lowest $9^{\circ}\cdot9$, on Feb-

ruary 2, 1884. During these months the extremes at Fort William were 73°·8 and 27°·0.

The barometric observations at Fort William and Ben Nevis were dealt with in a similar manner, and a table of corrections of the Ben Nevis observations to sea-level was constructed directly from the observations of the two stations, the table giving the approximate corrections for each tenth of an inch of the sea-level pressure, and for each degree of mean temperature of the stratum of air from the Observatory to sea-level, which was assumed to be the arithmetic mean of the temperatures at the two stations. The normals of atmospheric pressure for Ben Nevis were then calculated. The lowest normal monthly pressure is 25·141 inches for January, and the highest 25·410 inches for June, and for the year 25·281 inches. Comparing the normal pressures at the high- and low-level stations, pressure on Ben Nevis is on the mean of the year 4·557 inches lower than at the sea-level at Fort William, the least monthly difference being 4·484 inches in July, and the greatest 4·620 inches in February.

The morning maximum of pressure was at 10 a.m. in January, at noon in February and March, 1.30 p.m. in April and May, while in June it was delayed to 3 p.m. From Mr. Wragge's observations in 1882, the same diurnal phase of the pressure occurred about 9 a.m. in the summer months at Fort William, being thus six hours earlier than on the top of Ben Nevis. From February to June the morning minimum of pressure was very large. On the other hand, the afternoon minimum was comparatively small; and as the season advanced it became less and less pronounced, till in June the diurnal oscillation approached closely to one single minimum and maximum. Owing to the low readings of the morning minimum and the high readings of the afternoon maximum, which have their explanation in the diurnal change of the temperature of the aërial stratum below the level of the Observatory, the diurnal range of pressure on Ben Nevis exceeds that of any other meteorological station in Scotland.

The rainfall on the top of Ben Nevis is very large. At Fort William the mean annual amount is about 83 inches. During the three years beginning 1881, while the rainfall at Fort William was 24·59 inches from June to October, it was 47·10 inches on Ben Nevis. During the two years 1882 and 1883, for the same months, the rainfall at Fort William was 21·96 inches; at the lake (1840 feet high), 28·42 inches; but on Ben Nevis, 44·35 inches: hence during the summer months the rainfall on Ben Nevis is nearly double that of Fort William, and the greater part of the increase in the rainfall from Fort William to the top of Ben Nevis takes place above the level of the lake. No inconsiderable proportion of the large rainfall collected on the top is due to driving mists and drifting wet fogs, during which, though often no raindrops are visible, or only a few small drops at wide intervals apart, yet everything is dripping wet, and the funnel of the rain-gauge is crowded with numerous runnels of clear water, steadily trickling down into the receiver of the gauge.

On plains and extensive plateaux the wind attains a diurnal maximum velocity shortly after noon which is generally nearly double the minimum velocity, which occurs shortly before sunrise. But on Ben Nevis, in common with other observatories which are situated on peaks rising to a considerable height above the whole of the surrounding region, the reverse of this takes place, the maximum velocity occurring during the night, and the minimum during the day. The difference between the mean minimum and maximum hourly velocities on Ben Nevis in each of the seven months ending June last was about five miles. A tendency to a secondary maximum was shown in May, but in March, April, and June no such tendency was apparent. A full gale from south-east blew almost continuously at the Observatory from February 15 to 21, and during these seven days there was a mean maximum of 58 miles from 5 to 6 a.m. and a mean minimum of 42 miles from 4 to 5 p.m. With an hourly difference of 16 miles, the daily variation in the velocity of the wind was maintained during the continuance of this great storm.

Another main object in constructing the table of corrections to sea-level for Ben Nevis Observatory was to afford a ready comparison between the atmospheric pressure at sea-level and that on Ben Nevis from the important bearings of the observed differences on the changes of weather which precede, accompany, and follow storms, and on such inquiries as the singular and opposite relations which obtain during storms of wind and during the remarkable weather which often occurs within, or on the confines of, anticyclones.

ALEXANDER BUCHAN

THE FORESTRY EXHIBITION

SINCE our last notice of the International Forestry Exhibition great progress has been made in the concentration and arrangement of the various products which testify to the importance of the subject. We believe that the juries have now met, and such names as Sir Joseph Hooker, Colonel Moncreiff, R.A., Profs. T. R. Fraser of Edinburgh, Bayley Balfour of Oxford, Dr. Lyons, M.P., with several Indian and Scotch Forest Officials, and others will inspire confidence in their work. We to-day give a description of one of the most interesting sections, which well repays a visit.

The Japanese Court occupies the eastern transept, and forms one of the largest and most important sections. The whole arrangements have been carried out in the most thorough and business-like manner. Immediately on the arrival of their goods, knowing beforehand the amount of space required, and working with a rapidity and skill which might put to shame some more civilised nations, the Japanese Commissioners have shown that they are far in advance of many countries in business capacity as well as in the science of forestry. In Great Britain the importance of forestry to the welfare of the country and its colonies has but lately been recognised. In Japan, on the contrary, it has long formed an important feature in national education. This is evident from the ingenious devices represented on the walls of the department, and which can only have been the outcome of long experience.

With excellent taste the Japanese have placed the timber in the most prominent position, and the products in the background, giving at once the impression that it is purely a forestry exhibit. The central tables are occupied with longitudinal sections of trees, with the surface planed so as to render the grain visible. Above these are similar sections, but showing the bark, and above these are coloured drawings of the trees yielding them. At the foot of these sections a paper explains in English the Japanese name, the botanical name and habitat, and the relative rarity or abundance of the tree, its girth and height at fifty years old and at maturity, the best mode of propagation, the quality and uses of its wood and of other parts. Each section, drawing, and description is marked with a corresponding number. On the wall of the Southern Court are some artistic drawings in monochrome of the various devices for felling and floating the trees along mountain streams, for slipping them over precipitous cliffs, and for stopping and collecting the timber at certain localities in its course for storage. The expedients adopted for floating the timber down narrow gullies, and the sledges used for sliding it down over the snow in winter, and other details of forest work and a forester's life, are depicted in a manner that is easy to remember from the quaint dress, the life-like attitude, and excessive energy thrown into the actions represented. These drawings are mounted in wooden frames, and the background

tastefully decorated in a simple manner with fragments of veneer of different colours. They are accompanied by models which still better illustrate the means adopted in mountainous countries, and must prove exceedingly instructive to students of forestry.

Next in order come the tools used in the various operations of cutting, transporting, and working the timber and peeling the bark. Some of the axes and saws are of extremely peculiar shape, but admirably fitted for the purposes for which they are intended.

According to a printed table hung on the end wall, the area of the Japanese Empire is 38,563,718 chos (a cho = 2·450 acres), the area of forest (excluding the islands of Okinawa and Hokkaido) being 11,866,626 chos, or rather less than one-third of the country. Of this area 5,259,182 chos are worked by the Government, and 6,607,443 chos by private individuals. About a quarter of the Empire has, however, not yet been surveyed; the above figures, therefore, only refer to the surveyed portion. Accompanying this table is a map giving the distribution of trees in Japan, and marking out certain zones, each indicated by some particular tree forming a prominent feature in the landscape. Of these zones *Ficus Wightiana* characterises the lowest, *Pinus Thunbergii* the second; then follow in order *Fagus sylvatica*, *Abies Veitchii*, and *Pinus Cembra*. The extent of these zones is marked in colours on the map, and on excellent coloured drawings representing the habit of the five trees, and their foliage, flowers, and fruit in life-size are presented at one glance. The less important productions of the forests are appropriately illustrated by smaller collections, a simple expedient by which an idea of their relative consequence is easily conveyed. Fungi, dried and preserved in pickle, and a dried lichen (a species of *Gyrophora*), and a collection of seeds of forest-trees, well preserved, and carefully named, are placed near. Several fungi are cultivated on special trees. According to notes affixed to the tree-sections, among the trees thus employed are *Celtis sinensis*, *Carpinus laxiflora*, *Quercus crispula*, *cuspidata*, and *glandulifera*.

Roots, barks, and seeds used in medicine are not so well represented as usual. Even menthol, now tolerably well known in this country as a remedy for neuralgia, is not exhibited. A beautiful specimen of insect wax resembling spermaceti in appearance, but much harder, and identical with that used in China to coat candles to prevent their guttering, is exhibited. The insect producing it is cultivated on *Ligustrum Ibota* and *Fraxinus pubinervis*.

An exceedingly ingenious double chop-stick is here shown, consisting of a piece of white wood, slit two-thirds of its length; on pulling the pieces apart, a wooden toothpick is seen inclosed in the centre. As the wood has never been entirely split, it is puzzling to know how the toothpick was inserted. This is done by cutting it with a special instrument when the wood is wet and can be extended. The leaves of two other plants besides those of tobacco are shown, the one made into cigarettes, and the other simply dried for smoking (*Sterculia platanifolia*).

The cooperage work seems to be carefully done, the barrels having polished surfaces, and in some instances the bands are made of plaited bamboo. The polishing of rough surfaces appears to be effected by the rough leaves of *Aphananthe aspera* and the stems of a species of *Equisetum*. Japanese tooth-brushes are exhibited, made of the frayed-out ends of a piece of white wood; and combs, and even tooth-combs, are made of similar material of a harder character, such as the wood of *Olea Aquifolium* and *Hovenia dulcis*. Dyeing and tanning barks are comparatively few in number, and walking sticks do not present any great variety, only a few being engraved or ornamented. A simple flower-pot for the wall of drawing-rooms consists of two joints of a large bamboo, with a piece cut out at the side of each joint so as to permit of a fern or bouquet depending over it.

In the left-hand court may be seen some bent wood furniture that might fairly compete with that of Austrian manufacture. In one corner may be seen a series of young trees four or five years old, imported from France, Germany, the United States, and other countries; indicating that acclimatisation of the useful trees of other countries has already been commenced in Japan. Wood-engraving and printing in one or more colours is illustrated by the engravings placed side by side with the blocks. The celebrated Japanese lacquer is exhibited in the crude state, and also applied to knick-knacks and other articles, some specimens of lacquered slabs having so high a polish as to appear like glazed ornamental tiles. These are accompanied by a coloured drawing of the foliage and flowers of the lacquer-tree painted on the wood of the same tree and framed, with other portions having the bark attached. Several other useful timber-trees are illustrated in the same ingenious manner. The almost transparent yet strong and tough paper made from the fibre of the paper mulberry-tree (*Broussonettia papyrifera*) is shown, but its manufacture is not illustrated by drawings, the exhibits being limited to products. This paper rolled into the form of a spill is strong enough to be used like string. Exceedingly thin planed shavings of wood, scarcely thicker than the paper above alluded to, occupy a conspicuous position. These are used for packing butter or other goods of similar description. A cursory glance at the notes appended to the sections of wood reveals many interesting facts regarding some Japanese trees and shrubs commonly cultivated in this country. Thus an oil is obtained from the seeds of the common Camellia (*C. japonica*), and rope is made from the stems of *Wistaria sinensis*. Charcoal, for the manufacture of gunpowder, is prepared from the wood of *Paulownia imperialis*, and the wood of the deliciously scented *Olea fragrans* is used for wood-engraving and combs. A shrub, also indigenous in this country, *Viburnum opulus*, furnishes tooth-picks. A very ingenious use of the trunks of trees is the hollowing them out into drain-pipes, each about 6 or 8 feet long, and fitting into each other at the end. On the walls of this court illustrations are given of the mode of preventing the slipping away of soil on mountain-sides, and of the trees and shrubs and herbs useful for binding sandy soil or embankments, &c. Altogether the Japanese section is an exceedingly interesting one, and offers many useful suggestions to the foresters of Western countries.

PRACTICAL TAXIDERMY

AMIDST the many criticisms which are passed by visitors upon the collections in the new Natural History Museum of South Kensington, there is always to be found a word of praise for the improved appearance of the mounted animals in that Museum, and it may fairly be said that the encomiums which are heard on all sides have been justly earned by Dr. Günther and the staff of the Zoological Department; that is to say, if an honest endeavour to present to the public something better than can be seen in other museums counts for anything. The officers of the British Museum, in transferring the zoological collections from Bloomsbury to South Kensington, were heavily handicapped, for it was impossible to commence the mounting of the collections *de novo*, and they therefore had upon their hands a vast number of interesting specimens unfit to exhibit to the public, but valuable to the naturalist, and worthy of preservation as forming a historical part of that great zoological collection which is admitted by naturalists to be intrinsically the finest in the world. For some time before the removal a careful selection of duplicate specimens had been made, and these had been distributed to various provincial museums, but all those which possessed any scientific value, such as types, &c., have been carefully unmounted and added to the collection of skins, and it was curious

to note the progress of the art of taxidermy which these specimens exhibited. It is notorious that for many years the authorities of the Zoological Department have been troubled with the preservation of antique specimens of natural history which seemed to be falling into a state of natural decay, although no actual reason could be assigned for their dissolution, and moths and beetles have never been known to do any harm to the collections, thanks to the constant care which is exercised in that department. But on dismounting some of the ancient specimens, such as those presented by Colonel Montagu, it was discovered that they had never been properly skinned, and with the exception of the extraction of the entrails, the bones and flesh of the birds had been left entire, and apparently without an attempt to further preserve the specimens. The result may be imagined, and the difficulty of preserving these interesting relics will be fully appreciated by the naturalist of to-day. It has often been a source of wonder to zoologists as to what has become of many of the types of species recorded by Latham and the older writers on ornithology as existing in the British Museum, which certainly are no longer in the national collection. The records of the Museum show that they never descended to modern times, and there can be little doubt that the defective preparation of a hundred years ago was inadequate for their preservation, and that they were allowed to fall into decay by the earlier custodians of the national Museum, in whom the sacred value of a type was not so inherent as it is in the age in which we live.

We may hope that the improved preparation of the specimens in the Natural History Museum marks the commencement of a new era in the art of taxidermy, for the skilful mounting of animals is a real art, and ought to be recognised as such. An artist who portrays animal life successfully reaps the full appreciation of his countrymen, and is well paid for his work, but hitherto the taxidermist has never been properly appreciated, and until adequate remuneration is provided for the artists who reproduce natural specimens, we can never hope for the success of taxidermy as an art which ought to rank as high as that of the animal painter. The undoubted success which has attended the production of the groups of British birds which now adorn the corridors in the Natural History Museum is a great encouragement to those who have at heart the welfare of the art of taxidermy, and it cannot be denied that the mounting of these groups does credit to all concerned. We are aware that Prof. Flower (himself no mean taxidermist) takes a great interest in the improvement in the mounting of animals in the Museum of which he is so able a Director, and the exertions of Dr. Günther in this direction have been manifest since his appointment as Keeper of the Zoological Department in the British Museum, while the frequent occurrence of Lord Walsingham's name as a donor of many of these beautiful groups of "British birds in their haunts," shows the practical utility of having as a trustee a naturalist who labours to supply the wants of the institution of which he is one of the guardians. In the Bird Gallery itself, as well as in that of Mammalia and Osteology, the same wish to improve the natural appearance of the specimens exhibited is seen at every turn, and it is to be hoped that the lesson thus taught by the British Museum will be imprinted on the mind of every provincial curator, who will feel henceforth that the value of the collection under his charge will consist not so much in the array of mounted specimens which he can muster on his shelves, as in the excellent preparation of the few leading types which are really all that are necessary for the instruction of the public.

The above thoughts have been inspired by a perusal of a little work which has fallen into our hands, viz. the second edition of Mr. Montagu Brown's Essay on Taxidermy. Mr. Brown is the Curator of the Leicester Museum, and he is a man of whom any provincial museum may well be proud. In a lecture delivered many years ago at Leicester Mr. Bowdler Sharpe gave some hints on what he conceived it to be the object of a County museum. It seemed to him that in the first place it was expected of every County museum to make as perfect a collection as possible of the natural productions of that County—that this should be the aim and object of every curator, and that all these exhibits should be arranged in the most popular and attractive form. It was impossible, he pointed out, for a local museum to attempt to show a perfect collection of all the classes of animals. This ought to be left to the British Museum; but he insisted that it was within the province of every such museum to exhibit a typical series of animals which would be useful for comparison with local species, and would educate the minds of an intelligent public towards an appreciation of the varied forms of animal life upon the globe, as compared with the zoology and botany of the county in which they lived. Shortly after the Committee of the Leicester Museum carried out this idea to a limited extent under the curatorship of Mr. Harrison, a most intelligent custodian, who is, we believe, now located at Birmingham; but the plan was fully developed by his successor, Mr. Brown, who has employed his talents as a taxidermist in a popular direction, and the result is that the collection of birds at Leicester is mounted in cases with the natural surroundings explaining their habits at a glance, and in a manner with which no guide-book attempting to illustrate a collection on a conventional plan can hope to vie. It may be a question for naturalists whether this will not be the museum of the future, but as evidence of the value of practical taxidermy this may be considered already *un fait accompli*; and in making these remarks it would be unfair not to mention the names of some of those who in England have contributed to the improvement of this art. Of these the honoured name of John Hancock stands first, for the influence of Waterton, who strove to import into this country an improved system of mounting animals, seems to have been but small among the generation which followed him. Mr. Hancock's groups in the Great Exhibition of 1851 left an indelible impress upon British taxidermy, and his rendering of a bird of prey is only equalled for life-like delineation by one of Wolf's pictures. Mr. A. D. Bartlett, the well-known Superintendent of the Zoological Gardens, is certainly one of the best taxidermists which this country has produced, while the art of mounting Mammalia has been studied with success by Mr. Rowland Ward and Mr. Edward Gerrard most of the best examples of the latter class in the British Museum having been mounted by the last-named artist. Many provincial men, such as Mr. Swaysland of Brighton, Mr. Shaw of Shrewsbury, and Mr. Quartermain of Stratford-on-Avon, have proved their ability as taxidermists, and London itself possesses adepts in the art who are equal to the great taxidermist Termayer of Holland, whose masterpieces may be seen in the Museums of Amsterdam and Leyden; but we doubt whether anybody has exercised more influence on the improvement in the mounting of animals than Mr. E. T. Booth of Brighton, whose collection of British birds exhibited in the Dyke Road Museum is one of the sights of England. To him belongs the credit of being the first to attempt a collection of British birds with their natural surroundings, and it is upon the lines introduced by Mr. Booth that the beautiful groups of our native species in their natural habitats has been attempted at the British Museum; and if the genius of Mr. Pickhardt who has mounted the birds, and of Mr. Mintorn, to whose skill the beautiful modelling of the flowers and trees is due, does not satisfy the aspirations of British naturalists, we shall feel that the improvements in the taxidermy of recent years have no real existence.

NOTES ON THE CANADIAN NORTH WEST

THE excursion to the Rocky Mountains, along the Canadian Pacific Railroad, will probably prove a most attractive feature in connection with the British Association meeting this season. Living on the cars for several successive days and nights is a novel experience for most people, and one, it might be supposed, that would prove monotonous; but the alternation of forest, lake, prairie, and mountain scenery, each with its associated peculiarities, will probably prevent the trip becoming at all tedious. Some members of the Association may prefer taking the route through the United States to Winnipeg, but from thence all will proceed through the rich wheat lands of Manitoba, then over the rolling prairies west of Brandon, with their numerous alkali lakes and relatively unproductive soil beyond Moosejaw; through the cattle-ranching district at the eastern base of the Rocky Mountains, and up the winding Bow Valley to the summit-level in the Kicking Horse Pass. Here at Stephen, on the confines of British Columbia, the railway terminates for the present.

On crossing the prairies for the first time, many interesting peculiarities will arrest the attention; perhaps none so strongly as the general flatness and absence of timber, which as a rule only occurs skirting the rivers, or as a low scrub in certain wet or marshy lands, or in scattered individuals along the dry sand and gravel ridges. These are probably the patches of country that escape the prairie fires, owing to the vegetation being either too damp or too scanty to support a conflagration. Vegetation as a rule is luxuriant, especially on the rich lands, where the grasses grow to a great height. The soil is mostly a rich black loam of variable thickness, accumulating by the annual decay of the grasses or by the ash from the fires. The loam is thickest on those flat lands with clay subsoil that lie south of the Manitoba lakes: in the arid districts of the western sections it becomes very light.

The subsoil is for the most part stratified sand and subangular gravel, which often contain large boulders of gneiss and quartz; it appears to be in a great measure of glacial origin; but in many places, as in the vicinity of Winnipeg, the subsoil is a stiff brown clay which is probably the filling of an ancient lake: it is seen in the banks of the Red River and Assiniboine. In the high banks of the Saskatchewan at Medicine Hat the clay has more the appearance of a stiff boulder-clay.

A few miles up the River Saskatchewan from Medicine Hat there is an important outcropping of coal; another seam is exposed on the Bow River near Crowfoot Creek; but the most important is that on the Belly River, where there are active collieries, the fuel being conveyed down the river to Medicine Hat, whence it is distributed along the line of railway. These fuels are lignitic in character, and are considered to be either of later Cretaceous or early Tertiary age. They come to the surface in many localities, and evidently underlie a large portion of the western plains. Adjacent to the eastern face of the Rocky Mountains the strata in which the coals reappear are more indurated and highly inclined, and some of the beds contain silicified wood.

In the section of country between Moosejaw and Medicine Hat alkali lakes are numerous; the smaller ones evaporate during the dry season, leaving a flat surface covered by a thick, white, glistening deposit: from this district fine specimens of selenite are obtainable. Probably some of the largest of these bitter lakes are those called the Old Wives Lakes, which lie in a large, sterile depression, on Le Grand Coteau du Missouri, evidently representing the site of a former large inland sea. The fresh-water lakes and marshes, locally numerous along the track, generally teem with wild fowl. In many of them also the tall elevation of reeds, formed by the musk-rat, may be seen.

Of other animal life on the plains there is a great absence. However, the so-called "blackbird" or purple crakle (*Quiscalus*) is locally very abundant; during the early season they keep in pairs, but, on the ripening of the corn, immense flocks of them congregate about it; prairie chicken are also numerous, but of other birds there are very few. Snakes abound in some places; they are constantly to be seen basking in the sun along the railway track. Of mammals the most frequent is the little Gopher or "prairie dog." Almost the only other visible quadrupeds are foxes and a few antelope.

Of the former great numbers of the now practically exterminated buffalo there is abundance of evidence. Their wallowing holes and runs are seen in all directions; the latter, narrow furrow-like tracks, stretch in straight lines across the plains, being most numerous in the vicinity of water. Bleached bones and skeletons, which lie scattered about in great profusion, testify to the wholesale destruction effected, chiefly by the Indians and half-breeds. On the introduction of modern repeating rifles whole bands of buffaloes were ruthlessly slaughtered, solely for their tongues and skins, and often nothing save the tongues were taken from the carcasses.

This indiscriminate destruction has reduced the Indian of the plains to a state of the most abject poverty and destitution, for formerly most of his wants were supplied by the buffalo; now he is wholly dependent on the Canadian Government, which allows a grant to each individual for his support, amounting in all to about 200,000*l.* per annum. Alcohol is not permitted amongst them, and there is a very heavy penalty for bringing intoxicating liquors into the North-West Territories. Of the various tribes, Sioux, Crees, and Assiniboines are met on the eastern portions of the plains; the Blackfoot reserve is situated near the Blackfoot crossing on the Bow River, where an Indian supply farm has been established. The Sarsee reserve is near Calgary; and at Morley the Stonys have their reserve; the latter, however, migrate into the mountains early in the season, and spend the summer in hunting; and although game is now very scarce, they are better off in this respect than their brethren of the plains. From these they differ greatly in physique, being shorter and more thick-set. They are more tractable than many of the other tribes, and a mission has been for some time established among them at Morley.

The country of the plains does not appear to be wholly adapted for agricultural purposes; Manitoba and a great part of Assiniboia are very rich, producing magnificent crops of corn; but the most fertile belt appears to stretch away from Brandon towards Edmonton, the line of the railway traversing a less fertile district to the south. West of Moosejaw the agricultural prospects are indifferent, and in many cases very poor. About Calgary the season is short, but a good deal of cattle-ranching has been done, and the district is considered well suited for it, although two years ago about 75 per cent. of the imported cattle died; this mortality seems to have been the effect of bringing cattle from lower latitudes late in the season, as, on arriving, they were in such a poor condition that they were unable to bear the winter, which that year set in unusually early, and was particularly severe.

Further north, towards Edmonton, the climate is not considered to be so harsh as about Calgary: this is probably owing to the lower altitude of the mountains permitting the warm Pacific winds to be more beneficial.

Beyond Calgary the railway follows the valley of the Bow River through the district of the Foot Hills for a distance of about fifty miles, when it enters the Rocky Mountain by the Bow Pass at Padmore, or the Gap. Between Calgary and the mountains the character of the country is very different from the prairie districts: the surface is hilly, with patches of pine forest. The strata are more indurated and folded, being often highly inclined. Several well-marked river-terraces can be traced along

this valley, the uppermost extending far up the Bow Pass. In many districts on the plains the flies are so abundant as to interfere with surveying operations, alighting on the object-glasses in such numbers as to obscure the view. In all the houses the black flies literally cover everything. Earthworms do not occur in the north-west. To the botanist the plains are most attractive, there being an almost endless variety of grasses and pretty little flowers; many of our ordinary garden annuals growing wild over the plains.

To one who crosses the plains by the usual railroad route, the Rocky Mountains are first seen from near Crowfoot Creek, at the distance of about 150 miles. They appear as a serrated ridge on the south-western horizon, and numerous patches of snow can very soon be distinguished on them. The entrance to the Bow Pass, by which the mountains are entered, cannot be detected till one is close to the range. It is a comparatively broad winding valley, the direction of the bends being either south-west, across the strike of the strata, or north-west along that strike. The mountains rise precipitously on each side, but the valley itself presents a flat bottom, through which the river winds. This wide level plain, as a rule, is well timbered, the woods extending to a considerable altitude on the mountain sides; but forest fires have reduced the amount of available timber considerably. The trees are mostly either spruce or red fir, and, over the burnt areas, cotton-wood. Along the valley frequent large open untimbered spaces, locally called "parks," bear good pasturage. The removal of the timber from their surface was evidently effected by recurrent fires.

The strata which compose the mountains are regularly disposed, striking north-west and south-east, and having a regular dip to the south-west, which at the outskirts of the range is moderate, but gradually increases till the beds are almost vertical about Castle Mountain. Westwards, in the main divide, they lie more flat. The chief rocks are crystalline magnesian limestones, with calcareous slate, and locally, peculiar siliceous rocks containing opal; amongst the upper beds of the series there are quartzites, grits, and conglomerates.

Near Cascade Mountain an outlier of coal of the same age as the beds on the plains, but much more indurated, rests unconformably on the older rocks, showing that in all probability these Secondary or Tertiary rocks formerly covered most of this Palæozoic area. The older rocks which compose this part of the range are probably of Devonian or Carboniferous age; along the edge of the plains they are cut off by a large fault having a downthrow to the east, which brings the Cretaceous or Tertiary rocks into juxtaposition with them, while to the west they pass under newer strata. River terraces occur along the valley, and near Cascade Park there is a large accumulation of drift, apparently of glacial origin.

Many geologists will probably be disappointed in the Rocky Mountains of the Bow Pass section, for they hardly equal the familiar descriptions of the ranges further south. To the mineralogist, too, they promise but a poor field; the small amount of plication in the strata, and the absence of crystalline rocks, being unfavourable for the development of good mineral specimens. As to the industrial minerals, the resources of the valley have not yet been determined, but it appears that at least one metalliferous belt passes through the highly inclined rocks in the vicinity of Silver City: it bears copper pyrites and glance in veins running transversely to the general direction of the belt. Whether these veins are sufficiently rich, or whether there are large bunches of ore in the belt, has not yet been proved. Argentiferous galena is also known to occur in the grits and quartzites.

The climate of these mountains is very enjoyable in summer-time. During the day it is sometimes rather hot in the valleys, and the flies prove very troublesome, while at night there are often severe frosts. On the hills the temperature is much more equable, there being usually a cool breeze during the day, and at night the air feels warm and balmy. The timber line here is about 6000 feet above sea-level, and although it is only the highest peaks that rise above the line of perpetual snow, yet there are large accumulations of snow on the northern slopes and in many of the valleys, extending some distance below the timber line. On warm days snow-slides may be constantly heard descending with a loud roar. Glacial lakes occur in several of the valleys and cooms.

Fish abound, but they are difficult to catch except in the small rivers and lakes, where, however, they are small.

To the botanist the mountains would probably prove even more attractive than the plains, as there is such variety in the flora according to the altitude. Above the present timber limit vegetation rapidly diminishes, only scattered individuals occurring at a distance above it, one of the most remarkable of these being the forget-me-not, bright blue patches of it not uncommonly occur right up alongside the snow banks.

GERRARD A. KINAHAN

NATIVE AMERICAN LITERATURE AND ETHNOLOGY[1]

OUR apology for grouping together so many valuable works on native American literature must be the extraordinary rapidity with which such productions are accumulating. Unless dealt with in this somewhat summary way, they run the risk of not being noticed at all. The great activity recently displayed in this department is largely due to the personal efforts of Dr. Brinton, whose spirited attempt to form a "Library of Aboriginal-American Literature" has already made some progress towards realisation. The first book on our list is practically a reply to those who may be sceptical as to the existence of sufficient materials to warrant such an enterprise. Based on a paper laid before the Congress of Americanists at Copenhagen last year, it takes a summary but comprehensive survey of all the still extant monuments of native literature in the various branches of history, legend, ritual, oratory, poetry, and the drama. In some of these branches the quantity of available matter is considerable. Hundreds of native tales and legends have been committed to writing by the Christian Eskimo of Greenland, and Dr. Heinrich Rink's manuscript collection of their historical traditions fills over two thousand pages. But the quantity of folk-lore and tribal myths floating about in the oral state amongst the Dakotahs, Athabascans, Algonquins, and other North American nations is alone sufficient to supply abundant materials for Dr. Brinton's undertaking. These, however, cannot be properly utilised until the natives have been educated and taught to write their own language, as, for instance, some of the Eskimo, Cherokees, and Iroquois have already learnt to do.

A brilliant result of such education is the "Iroquois Book of Rites," second on our list, which is now printed for the first time from native manuscripts recently brought to light by the editor, Mr. Horatio Hale. In the introduction a curious account is given of these manuscripts, of which there are three extant, two in the Canienga dialect procured at the Iroquois Reserve near Brantford, and one in the Onondaga dialect found at the Reservation near Syracuse, New York. The former are duplicate copies of the "Book of Rites" proper, and one of them appears to be traceable to an original, composed during the latter part of the last century, probably by the

[1] "Aboriginal American Authors." By Daniel G Brinton, M.D. (Philadelphia, 1883.)
"The Iroquois Book of Rites." Edited by Horatio Hale, M.A. (Philadelphia, 1883.)
"The Güegüence: A Comedy Ballet in the Nahuatl-Spanish Dialect of Nicaragua." Edited by D. G. Brinton. (Philadelphia, 1883.)
"Sixteenth and Seventeenth Annual Reports of the Peabody M[illegible] of American Archæology and Ethnology." (Cambridge, 1884.)

Canienga Chief, David of Schoharie. The other, written by one "John Green," of the Mohawk Institute at Brantford, and dated November 1874, is based on an unknown text differing in some respects from that attributed to Chief David. The Onondaga is not a copy of the Canienga work, but its complement, comprising the speeches addressed by the younger to the elder nations when a chief of the latter is mourned, and hence named the "Book of the Younger Nations." All the original texts may possibly have been composed about the middle of the eighteenth century, by which time several of the natives had been sufficiently instructed by the English missionaries to read and write their mother tongue fluently.

Such is briefly the history of the "Book of Rites" in its written form, which consists mainly of the speeches, songs, formulas, and ceremonies performed at the meetings of the Great Council, or "Council of Condolence," of the Iroquois Confederacy, when it met for the combined purpose of mourning the death of a chief and celebrating the induction of his successor. The proceedings to be observed on this important occasion had evidently been handed down orally from the time of the formation of the famous League, or "Great Peace," an event usually referred to the middle of the fifteenth century. Much of the contents of the "Book of Rites" may therefore fairly claim to date from that period. But although the strictly ceremonial portions may have been written down in the very words in which they had been orally preserved for some three hundred years, the text as it now stands has obviously been coloured by the spirit of the eighteenth century, and is, so far, not a faithful reflection of the social ideas and inner life of the Iroquois nation in pre-European and pagan times." Such passages as "The Great League which you established has grown old"; "Hail, my grandsires! You have said that sad will be the fate of those who come in the latter times": "ye are in your graves who established it [the League]. Ye have taken it with you and have placed it under you, and there is nothing left but a desert," were written by men who felt that the Confederacy was already a thing of the past. The whole tone of the work is in fact pervaded by a spirit of sadness and despondency, and its very scope seems to have been the preservation of the empty forms and ceremonials of an institution whose days were already numbered. This point should be borne in mind in reading the comments of the editor on the present text, and especially the arguments drawn from it in favour of the superiority of the Iroquois race over "the Aryans of Europe" in humanity, public spirit, and political sagacity. The curious theory is even advanced that the fine qualities of the European Aryan, as compared with his barbarous Asiatic kindred, "may have been derived from admixture with an earlier population of Europe, identical in race and character with the aborigines of America" (Introduction, p. 98). And in an unfortunate appendix, where this idea is worked out at some length, it is suggested that the time is approaching when the "servile Aryans will cease to attract the undue admiration which they have received for qualities not their own; and we shall look with a new interest on the remnant of the Indian race, as possibly representing this noble type of man, whose inextinguishable love of freedom has evoked the idea of political rights and has created those institutions of regulated self-government by which genuine civilisation and progress are assured to the world" (p. 190).

Mr. Hale is more instructive in the section of his erudite introduction devoted to the genius and inner structure of the Iroquois language. Here he shows, against the general conclusions of philologists, that Iroquois really abounds in true abstract terms. Such are *otariténsera* = heat, *atariatitsera* = courage, *kanaiésera* = pride, *kanakwensira* = anger, regularly derived by the affix *sera* from verbal forms. He also makes it clear that true grammatical gender exists, forming, as in the Semitic system and in some neo-Sanskritic idioms, a distinctive feature of verbal conjugation. But its use is entirely restricted to the third person singular, dual and plural, as in *watkahtos* = she sees, *kiatkahtos* = they two see (fem.), *kontkahtos* = they see (fem.). This point is of great importance as affecting the various psychological systems of linguistic classification that have been proposed by certain German theorists. It may be incidentally remarked that in Africa also the distinction between gender (Hamitic) and non-gender (Negro) languages no longer holds good; for it now appears that gender is also characteristic of the Masai, and of many Nilotic negro tongues.

Dealing with the tendency of Iroquois and so many other American languages to fuse the terms of the sentence into a single compound word, Mr. Hale observes: "The notion that the existence of these comprehensive words in an Indian language is an evidence of deficiency in analytic power, is a fallacy long ago exposed by . . . Duponceau. As he has well explained, analysis must precede synthesis. In fact, the power of what may be termed analytic synthesis—the mental power which first resolves words or things into their elements and then puts them together in new forms—is a creative or co-ordinative force indicative of a higher natural capacity than the act of mere analysis. The genius which framed the word 'teskenonhweronne,' ['I come hither again to greet and thank'] is the same that, working with other elements, produced the steam-engine and the telephone" (p. 150). Here again it is to be feared that bias has got the better of reason. Certainly the world would have had to wait very long indeed for the steam-engine and the telephone had their invention depended on the natural evolution of the people who "framed the word" in question. Prof. Sayce ("Science of Language") has also made it tolerably evident that analysis does not precede synthesis, and that the unit or starting-point of speech is rather the sentence than the word. Hence the American polysynthetic is an infantile compared with the English analytical process in the example appealed to. But, apart from these eccentric views, it is a great pleasure to be able to say that Mr. Hale has given us an admirable edition of the "Book of Rites"—a priceless treasure opportunely rescued by him from the imminent danger of destruction.

An equal share of praise is due to Dr. Brinton as editor of the "Güegüence," which forms the third volume of his Library Series. This curious document presents considerable interest, both from the ethnological, philological, and literary points of view. An original native drama in the strict sense it can hardly be called. But although dating no further back than the last century, and composed in a strange medley of bad Spanish and Nahuatl (Aztec), it may be regarded as almost the last surviving specimen of the aboriginal semi-dramatic compositions which appear to have been in common use amongst the Central American peoples long before and after the Conquest. Such compositions, prepared for oral recitation at the public feasts and ceremonies, were so far dramatical that they took the form of dialogue, and turned on some simple incident with a happy *dénouement*. In the present instance the Guegüence, that is, the elder or village headman (from the Aztec "*huehuentzé*" = "dear old man"), is brought with his two sons before the provincial governor, charged with entering the province without a permit. This leads to a good deal of repartee, some broad jokes, and intentional misunderstandings on the part of the hero, who in the end comes off best and manages to bring about a marriage between one of his sons and the governor's daughter. The language of the piece is very peculiar, and will doubtless be appealed to by the advocates of mixed forms of speech in favour of their views. Yet a careful study of the text shows that here the Spanish and Aztec elements are not harmoniously fused, as are, for instance, the Saxon and Latin elements in

English. Thus we have sometimes two or three tolerably correct consecutive Spanish sentences with due observance of its grammatical forms, as, for instance, Pues, tome! Uno, dos, tres, quatro. Ha! mi plata, muchachos! Cuatro cientos y tantos pesos le he dado á mi amigo Cap^n Alguacil. But beyond abrupt exclamations such as "*Mascamayagna, Güegüence*" = "at your service, Güegüence," complete grammatical Aztec sentences never occur, and the composition may on the whole be regarded as essentially Spanish copiously interlarded with native words and phrases. Hence it is rather a medley than a true *lingua franca*, or a jargon, such as "Pigeon-English," and the Chinook of the Columbia river, which involve a total destruction of the relational forms of all the constituent elements, thus preparing the way for a fresh grammatical departure. Thus only is it conceivable that true mixed languages can be developed, and the conditions favourable for such combinations are necessarily so exceptional that they must in any case always remain the rarest of linguistic phenomena.

Little space is left to speak of the last "Reports of the Peabody Museum," which are more than usually rich in original ethnological materials. Conspicuous amongst these are the graphic descriptions at first hand of the "White Buffalo Festival of the Unepapas," the "Elk Mystery or Festival of the Ogallala Sioux," the "Religious Ceremony of the Four Winds as observed by the Santee Sioux," the "Shadow or Ghost Lodge: a Ceremony of the Ogallala Sioux," and the "Wa Wan or Pipe Dance of the Omahas," all by Miss Alice C. Fletcher, who has recently been spending some profitable time in the midst of these North American tribes. By taking up her residence amongst them, sharing in their domestic joys and sorrows, making herself one of them, this enterprising and benevolent lady has enjoyed rare opportunities of penetrating into the inner life of the aborigines. Hence the great value of her remarks, especially on their religious views, a correct appreciation of which can only be had in this way. On the vexed subject of nature-worship and animism some current misconceptions are combated and fresh light thrown on the attitude of the native mind towards the outward and invisible world. "Careful inquiry and observation," she writes, "fail to show that the Indian actually worships the objects which are set up or mentioned by him in his ceremonies. The earth, the four winds, the sun, moon, and stars, the stones, the water, the various animals, are all exponents of a mysterious life and power encompassing the Indian, and filling him with vague apprehension and desire to propitiate and induce to friendly relations. This is attempted not so much through the ideas of sacrifice as through more or less ceremonial appeals. More faith is put in ritual and a careful observance of forms than in any act of self-denial in its moral sense as we understand it. . . . To the Indian mind the life of the universe has not been analysed, classified, and a great synthesis formed of the parts. To him the varied forms are all equally important and noble. A devout old Indian said: "The tree is like a human being, for it has life and grows; so we pray to it and put our offerings on it that the god may help us." Here we have placed in a vivid light the very essence of Anthropomorphism—ultimate base and starting-point of all primitive religions.

In the Curator's Report reference is made to the imprints of human feet discovered by Dr. Flint on December 24, 1883, in the volcanic rock some fourteen feet below the surface soil in Nicaragua. The tracks are in several series running nearly parallel with the banks of Lake Managua, within 300 feet of the present margin. Above the prints is a bed of clay and volcanic material containing fossil leaves, and over this four distinct beds of more recent volcanic matter. Blocks of rock containing the prints have been cut away and forwarded to the Museum. "That they were made by the feet of men while the material of which the rock is formed was in a plastic condition there is not the least doubt. The imprints are from nine to ten inches long and about four wide across the ball of the foot . . . with heel-ball and toes perfectly distinct. Dr. Flint states that the stride was only from eleven to eighteen inches, which indicates slow walking over the plastic substance." It is hoped that a clue to the geological age of the deposit may be obtained from the fossil leaves, a report on which is expected from Prof. Lesquereux. A. H. KEANE

NOTES

THE International Conference on Education was opened at the Health Exhibition on Monday by the address of Lord Carlingford, and has been continued during the week. There is a very large attendance both of English and foreign educationists, while the papers and discussions have been of much interest and importance. We hope to speak in detail of the Conference in our next number.

THE summer meeting of the Institution of Mechanical Engineers began at Cardiff on Tuesday with the address of the president, I. Lowthian Bell, F.R.S. The papers to be read are all of a technical nature. The meeting will be continued during the week, and many excursions have been organised, and visits to engineering and other works.

THE French Association for the Advancement of Science will hold its next meeting at Blois from September 4 to 11 next. The lecturers and subjects of lectures have not yet been decided upon.

DR. SCHWEINFURTH will return to Africa in a few weeks, on a commission from the Berlin Academy of Sciences; but the field of his exploratory labours has not yet been finally selected.

THE Government having decided to appoint a Royal Commission for the Exhibition of India and the Colonies, which is to be held in London in 1886, the Prince of Wales has issued a certain number of invitations to those persons whom it is desired should serve on this Commission.

THE death is announced of Mr. Charles Manby, F.R.S., M.Inst.C.E., for forty-five years identified with the Institution of Civil Engineers, for seventeen as the paid secretary, and for twenty-eight years as the honorary secretary. He was born on February 4, 1804, and was the eldest son of Aaron Manby, the founder of the Horseley Iron Works in Staffordshire, and later of the Paris Gas Works, and of ironworks at Charenton, near Paris, and who re-organised the now famous ironworks at Creuzot. For his father he was also engaged on the design and construction of the first pair of marine engines with oscillating cylinders, upon the building of the *Aaron Manby*, the first iron steamship that ever made a sea voyage, and upon the several works in France before enumerated. In 1839 he was appointed secretary of the Institution of Civil Engineers, and soon afterwards threw himself, heart and soul, into a movement which revolutionised the Society. As evidence of the appreciation in which he was held it may be mentioned that when, in 1856, he relinquished the position—which has since been filled by his pupil, James Forrest—he was presented with a service of plate and a sum of two thousand guineas, "as a token of personal esteem, and in recognition of the valuable services he had rendered to the members individually and collectively." Again, in 1876, Charles Manby received from the members of the Institute of Civil Engineers a silver salver and a purse of upwards of 4000*l*. "in friendly remembrance of many years valuable services."

ON Monday, August 4, taking advantage of Bank Holiday, the Essex Field Club held a meeting at Colchester. The party,

about fifty or sixty in number, were met at the station by Mr. J. Horace Round, who conducted them through the older parts of the town to the Castle, the history of which was lucidly sketched and the main points of interest shown by Mr. Round. A hurried visit to the Castle Museum, with its splendid collection of local antiquities and natural history objects, was next made under the guidance of the Rev. C. L. Acland and Mr. Round. The party then proceeding to lunch at the Cups Hotel. After lunch, a drive of about eight miles along the Mersea Road, passing through the villages of Abberton and Peldon, the scenes of the earthquake of April 22, brought the party to West Mersea, where Mr. H. Lauer addressed them upon the history of this and the surrounding districts during Roman times, suggesting that the Roman town of Othona may have been situated on the opposite shore of the River Blackwater in the neighbourhood of Bradwell. Mr. Lauer next called attention to the interesting and mysterious "salting-mounds" or "red hills," which occur also on the Norfolk coast and along the rivers in Suffolk and Kent, and of which eighteen still exist between Strood and Virley in Essex. These, according to Mr. H. Stopes, F.G.S., often cover as much as 10 to 30 acres, and are from 2 to 4½ feet deep, being composed of red burnt clay mixed with rude broken pottery, charcoal, ashes, and often bones. A ramble eastward along the coast of Mersea Island brought the party to the "decoy" for the capture of wild-fowl, the working of which in former times was explained by Mr. Lauer. Here Mr. J. C. Shenstone gave a short demonstration of the interesting coast flora. Driving homewards the party stopped at the ruins of Langenhoe Church, wrecked by the earthquake, where Mr. R. Meldola gave a short statement on this subject in anticipation of the detailed report which he proposes to present to the Club. He stated that the area of structural damage covered about fifty square miles. After tea an ordinary meeting was held, Mr. R. Meldola in the chair, and the evening concluded with a *conversazione* at the Hotel, collections of insects, dried plants, and living insectivorous plants being exhibited by Mr. W. H. Harwood, Mr. Shenstone, and Dr. Alexander Wallace. The Mayor and many of the townspeople were present during the evening to listen to the short addresses on natural history subjects given in explanation of the various exhibits.

THE repeated failures of steamers to reach Siberia from Europe do not seem to have deterred M. Sibiriakoff, the well-known Russian merchant, from again despatching two steamers this year. Early last month the steamers *Nordenskjöld* and *Obi* left Tromsö (Norway) to attempt, it is stated, for the last time to reach Siberia. When in lat. 70° 55′ N. and long. 52° 15′ E. the engines of the *Nordenskjöld* broke down, and she was with great difficulty towed back to Vardö.

A SUBSCRIPTION has been opened at St. Petersburg, in order to raise the money for instituting at the University five bursaries in the name of Charles Darwin, to be employed for the maintenance of five students in the five chief branches of natural science.

THE Russian review, *Russkaya Starina*, and the *Jou nal* of the Russian Chemical and Physical Society have lately devoted some attention to the first steam-engine that was made in the Russian Empire, in 1763, at the ironworks of Barnaoul, in Western Siberia, by a mining engineer, Polzunoff. It appears from M. Woyeikoff's description of this steam-engine, the model of which exists still at Barnaoul (both reviews have figured it on plates), that Polzunoff's engine was a reproduction of the "fire-engine" of Newcomen, with some original improvements. Thus it has two cylinders, instead of one, and, instead of the beam, Polzunoff made use of a wheel which received the chains of the pistons, and transmitted the circular movement, transformed again into a rectilinear one, to a pair of bellows, used for blowing air into a high furnace. The distribution of vapour was automatic, as in Newcomen's engine, but with several improvements. The engine, which had cylinders 9 feet long and 9 inches in diameter, worked during two months from May 20, 1766, and 3100 cwts. of silver ore, yielding 5 cwts. of silver, were melted with its help. But Polzunoff did not see his engine at work, as he died from consumption four days before. He obviously was a remarkable man for his time, several of the physical remarks he made in the description of his engine showing not only a wide knowledge, but also a serious spirit of true physical reasoning, together with a notable skill for determining the limits of knowledge of that time. In his theoretical remarks about "Air, Water, and Vapour," he notices also that physicists are not yet agreed as to the origin of heat, some of them seeing in it a much-divided, fine moving matter, while others "see the origin of heat in friction and in the vibratory motion of the particles inaccessible to our senses, of which the bodies are constituted." He obviously quotes here the words of Lomonosoff, who stated in these very words the mechanical origin of heat in his most remarkable but unhappily little-known memoir, written as an instruction to Tchitchagoff's Polar Expedition.

SEVERAL severe shocks of earthquake were felt on Sunday afternoon at Foca, in Bosnia. The duration of each shock was over two seconds.

A BROCHURE just issued by M. Ch. Montigny at Brussels contains in convenient form the result of his studies on the state of the atmosphere as affecting stellar scintillation, with a view to forecasting the state of the weather. From the fact determined by W. Spring, that the colour of pure water in great bulk is blue, he explains the predominance of this colour in the scintillation of the stars just before and during wet weather. The luminous rays, he argues, traversing the air charged with large quantities of pure water are necessarily tinged with the blue colour of this medium. The excess of blue thus becomes an almost certain means of predicting rain. This theoretic conclusion corresponds with the results of his observations continued for several years past on the appearance of the stellar rays in connection with the state of the weather. During the few months of fine weather in the present year blue has been much less conspicuous than in the corresponding months of previous years since 1876, when wet weather prevailed. It also appears that green, which had always coincided with clear skies during the fine years before 1876, has recently again become predominant. Hence he thinks it probable that we have got over the cycle of bad seasons, and that dry weather and more normal summers may be anticipated at least for some time to come.

PROF. F. NEESEN publishes a reprint of his paper in the *Archiv für Artillerie- und Ingenieur-Offiziere* for 1884 on a generalisation of Sebert's method of registering the velocity of shot within the tube of a gun. Sebert's apparatus necessarily registers for a space somewhat shorter than the diameter of the ball. This defect is remedied and the registration extended to the whole length of the tube by means of a revolving appliance to which the registering tuning-fork is attached, and disposed parallel with the periphery of the cross-section of the shot. Pencils fastened to the prongs of the tuning-fork and vibrating with it are thus made to describe curves indicating the velocity of the ball in its course through the tube. The only objection to the process, which is made perfectly clear by several accompanying illustrations, is that by the concussion the registering apparatus may get deranged or jammed with the shot. This danger it is proposed to obviate by making the apparatus of the best steel, and diminishing the effect of the concussion by filling the shot with some fluid when fired for experimental purposes.

IN the last number of the *Bollettino* of the Italian Geographical Society, Dr. G. A. Colini continues his valuable

paper, already noticed in NATURE, on the Indians of the Upper Amazon regions. Much original and curious information is supplied regarding the Caribos, Shipivos, Amahuacs, Campas, Shetevos, and many other Christian and Pagan tribes, especially of the Ucayali and Huallaga basins. Thus we are told that most of the Christian women in the Ucayali villages don a European smock to attend mass, but after the service lay it aside for the native *pampanilla*, a scanty garment, white at first, but afterwards dyed blue or red with geometrical designs to save the trouble of washing it. Here also the men carefully pluck out the beard with pincers made of two shells, because the women consider this appendage as a sign of old age. Hence bearded youths are regarded as superannuated, while clean-faced old men are still eligible in the matrimonial market. The South American Indians are usually described as altogether beardless, an inference due probably to this custom, which appears to be very general.

THE principal articles in the current number of *Petermann's Mittheilungen* are on Arctic subjects. Prof. Mohn of the Norwegian Meteorological Institute writes on the hydrography of the Siberian Arctic from the observations of the *Vega*, while Lieut. Hovgaard, a member of the expedition, contributes a paper on the ice in the Kara Sea, and M. Lauriasen of Copenhagen on the point reached by Behring in his first expedition. In addition to these we have papers on the names of places in the Niger region, on the new map of Germany prepared by the general staff, and the usual notes.

THE plague of rabbits in our Australasian colonies is one of which much has been heard, and it appears that another European animal, the dog, is about to follow the example of the rabbit, and make himself a pest in place of a pet. It appears that the number of wild or semi-wild dogs has recently increased largely in Victoria and New South Wales, and the consequence is a great slaughter of sheep by these nomads. The Government has already offered rewards for their destruction. In New Zealand some enterprising people have hit on the idea of importing weasels and stoats from England to keep down the rabbits; but if the former increase in their new habitat as rapidly as the latter have done, the last state of New Zealand will be worse than the first, for a plague of rabbits must be as nothing compared to a plague of weasels, and a great increase of the latter, from their predatory and destructive habits, must be followed by a considerable alteration in the distribution of the fauna of New Zealand. In Jamaica, according to the last report of the Director of Public Gardens in that colony, the planters suffered greatly from the depredations of rats among the sugar-canes. The rat-eaten canes were good for nothing except rum, and accordingly large sums were spent in poison and dogs to keep down the rats, but apparently without much success. At last an enterprising planter determined to import the mongoose from India to destroy the rats on his sugar estate. The sugar-planters, Mr. Morris says, have unquestionably benefited greatly by its introduction, and rat-eaten canes are now hardly known where formerly they were found in large quantities. But the new importation continues to multiply and spread, not only on sugar estates, but on the highest mountains, as well as along shore, even amidst swamps and lagoons; and when the sugar-cane rat is wholly exterminated, the mongoose will still go on increasing, and what then? Must the colonists find something else to exterminate the mongoose, and save their poultry, and so on *ad infinitum*? As it is, negro settlers and persons not connected with sugar estates complain of its ravages amongst their poultry and even accuse it of destroying fruit and vegetables; and, although Mr. Morris doubts whether these complaints are all well founded, he acknowledges that the mongoose is the cause of great disturbance in the animal life of Jamaica. Harmless yellow and other snakes, lizards, ground-hatching birds, rabbits, and many members of the indigenous fauna of the island are likely to become extinct at no distant date. It will be interesting to watch the effect of the introduction of the mongoose, and we hope Mr. Morris will enlighten us from year to year on the subject.

AT the last meeting of the Asiatic Society of Japan (as reported in the *Japan Weekly Mail*) a paper was read by Dr. Whitney on "Medical Progress in Japan." The first era in Japanese medicine was the mythological age, when the treatment of disease appears to have consisted in the use of charms and the employment of the simplest remedies originated by the "Great-name-possessing Deity"; the next period covers nearly 900 years from the middle of the second century B.C., during which Corean and Chinese medicine was introduced, as well as Buddhism and the useful arts. At the close of the eighth century the University and a medical school were established, and here commences the third period in the history of Japanese medical progress, which lasts down to the middle of the sixteenth century. In the medical college of those days the students pursued a seven years' course, and appear to have received a thorough and systematic training in Chinese medicine, which, as then taught, was embodied in works consisting chiefly in numerous dissertations and philosophical deductions based upon incorrect notions as to the anatomy of the human frame and the relation of its various viscera with one another and with the different phenomena of nature. In the fourth period, from the middle of the sixteenth century, when the Portuguese first appeared in Japan, down to the restoration of 1867, occurred the revival of both the Japanese and Chinese schools, and the introduction of Western medicine, which appears to have played no unimportant part in the temporary success of the missionaries. They received at one time a grant of 7500 acres of public lands for the purpose of cultivating medicinal plants. In 1775 was published the translation into Japanese of a Dutch work on anatomy, which was the first of its kind published in Japanese. Vaccination was introduced in 1824 from Russia by some Japanese fishermen, and in 1858 a medical school was founded in Nayaski, in which Western medicine only was taught. With the effects of the revolution of 1868 on medicine, as on most other things in Japan, most people are familiar. The physicians and surgeons of new Japan are required to go through a three years' course of study, and to pass examinations in the manner familiar in Europe. Apothecaries, dentists, and midwives must similarly be provided with diplomas, which can only be obtained after satisfactory examination. Contagious diseases acts, the examination of drugs, a strict control of the sale of opium for medicinal purposes, and the numerous other measures by which governments seek to protect the public health, are now found in full working order in Japan.

DR. R. LENZ describes, in the last *Bulletin* of the St. Petersburg Academy of Sciences, a new application of the telephone to the measurement of temperatures at a distance. Let us imagine two stations, A and B, connected together by an iron and an argentan wire, which are looped together at both stations. If the looping at A has a different temperature to that of B, a thermal current will circulate through the wires; and if a silent interrupter and a telephone be introduced into the system, the telephone will emit a sound, which will cease immediately the observer at B has raised or lowered the temperature of his looping place, so as to render it equal to that of A, and to destroy thus the thermal current. The exactness of this method depends on the exactness of determination of the moment when the lull ceases in the telephone, which moment is influenced by a remnant of lull in the instrument after the equalisation of temperature at both ends of the apparatus. In a series of experiments where the points A and B were one metre distant, Dr. Lenz

determined temperatures by this method with great accuracy, the errors being only from 0°·01 to 0°·17; and he concludes that, by using iron-argentan wires two millimetres thick, the measurements could be made at a distance of five kilometres, which distance could be still increased, say to twenty-five kilometres, if antimony and bismuth wires were used.

THE last number (12) of the *Journal* of the Straits Branch of the Royal Asiatic Society has the continuation of a paper on Malayan Ornithology, by Capt. Kelham, and an official report by Mr. L. Wray, of Perak, on gutta-producing trees. Mr. Maxwell writes on "Shamanism in Perak," the term in this instance being applied to the incantations and ceremonies employed by the Malays to cure the sick. But surely Shamanism in its home in Thibet is something more than this. Mr. Ferguson contributes some notes on the curious changes which consonants undergo in passing from one Malay dialect to another. The papers, properly so called, conclude with a report on the Meteorology of the Straits. In the Annual Report of the Council of the Society we notice that it is intended to republish in a collected form valuable papers published in the Eastern Archipelago at one time or another, but now either out of print or difficult of access; also a text-book of the geography of the region, under the editorship of members of the Society, and a skeleton map of the Malay Peninsula, on a scale of a quarter of an inch to a mile, upon which all new information will be entered from time to time as exploration advances.

SEVERAL honorary promotions have been recently made by the French Government for scientific services. Dr. Cornelius Herz, director of *La Lumière Electrique*, has been nominated Commander in the Legion d'Honneur at the request of M. Cochery, Minister of Postal Telegraphy, for his works on Electricity. The Minister of Public Instruction has appointed Madame Camille Flammarion an officer of the Academy for having acted as a secretary to her husband in all his work in connection with astronomy. The Municipal Council of Paris has decided that one of the new streets of the Thirteenth Arrondissement shall be named Giffard, in commemoration of the inventor of the injector.

AN experiment has been made in Vienna which proves that even with incandescent lights special precautions must be taken to avoid any risk of fire. A lamp having been enveloped with paper and lighted by a current, the heat generated was sufficient to set fire to the paper, which burnt out and caused the lamp to explode.

ON July 27 there was celebrated at the Trocadéro Palace the centenary of the death of Diderot, the celebrated French philosopher, who was also a man of science in his time and editor of the famous *Encyclopædia*.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Miss A. E. Sturge; a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by the Rev. T. Rickards; a Common Fox (*Canis vulpes*), British, presented by Mr. Thomas Legg; a King Vulture (*Gypagus papa*) from South America, presented by Mr. August Strunz; two Red-tailed Buzzards (*Buteo borealis*) from Jamaica, presented by Mr. D. Morris; a Martinique Waterhen (*Ionornis martinicus*), captured at sea, presented by Mr. A. Jones; two Jackdaws (*Corvus monedula*), British, presented by Mrs. Frank; a Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. G. Westrup; a Crested Curassow (*Crax alector*), an Anaconda (*Eunectes murinus*) from British Guiana, presented by Mr. G. H. Hawtayne, C.M.Z.S.; a Grey Amphisbæna (*Blanus cinereus*) from Portugal, presented by Mr. W. C. Tait, C.M.Z.S.; a Golden-crowned Conure (*Conurus aureus*) from South-East Brazil, deposited; a Black Hornbill (*Sphagolobus atratus*) from West Africa, purchased; a three-quarter bred Mesopotamian Deer (between *Dama mesopotamica* ♂ and hybrid *Dama vulgaris*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE NEW COMET.—A circular issued from Dun Echt on July 31, contains the following approximate elements of the comet discovered by Mr. Barnard on July 16, calculated by Mr. S. C. Chandler of Harvard College Observatory:—

Perihelion passage, 1884, August 17·63 G.M.T.

	°	′
Longitude of perihelion	302	4
,, ascending node	357	52
Inclination	7	2
Logarithm of perihelion distance	0·14780	

Motion—direct.

The comet will probably be observable in this country after perihelion passage, as will appear from the subjoined positions resulting from Mr. Chandler's orbit:—

12h. G.M.T.	R.A. h. m.	N.P.D. ° ′	Distance from Earth	Intensity of Light
September 3	18 27·2	123 8	0·682	1·06
,, 7	18 44·2	122 6	0·701	0·98
,, 11	19 0·2	120 58	0·722	0·91
,, 15	19 15·9	119 46	0·747	0·83

At discovery on July 16 its distance from the earth was 0·627, and that from the sun 1·480, consequently the intensity of light was 1·16.

The supposition that this comet had been observed at Melbourne, Madras, and the Cape, arose from a mistake in telegraphing. M. Trepied (Algiers) calls it "nébulosité sans queue; condensation centrale."

PERIODICAL COMETS IN 1885.—During next year three comets of short period will return to perihelion. Encke's comet is due in March, probably in the first or second week, according to the elements of 1881. The next is Tempel's comet, 1867 II., in the case of which it is not possible to assign the time of perihelion passage without the calculation of the perturbations due to the attraction of Jupiter, near which planet the comet was situated during the last half of the year 1881; the least distance of the two bodies having been about 0·57 in October. The third comet referred to is Tuttle's, last observed in 1871, the perihelion passage probably in September or October.

A VARIABLE-STAR IN AQUARIUS.—Attention has been already directed in this column to a star, the position of which for 1884·0 is in R.A. 22h. 29m. 48s., N.P.D. 98° 12′·4, on the score of variability from the ninth magnitude to invisibility, or at least to below the twelfth magnitude. Mr. Knott has just made an observation which confirms the variation of the star, as notified by Mr. Hind some thirty years since. On August 1, by the method of gauging, Mr. Knott found its magnitude 11·7. It was 9m. according to the Markree Zones on October 27, 1848, and on four occasions was estimated 9·5 at Bonn. It was considered a ninth magnitude, probably in August 1855, at the late Mr. Bishop's observatory. Generally it seems to have been about 11·5m. There is some reason for supposing that it does not continue very long at maximum. Argelander was inclined to think that there was a mistake as to the variability of this star, but the evidence in favour of it appears now to be too strong to be thus set aside. It has not been included in Schönfeld's catalogues of known or suspected variables.

PTOLEMY'S 30TH OF CENTAURUS.—In Sûfi's "Description of the Stars," according to Schjellerup, we read: "Ptolemy has reported that there are in this constellation (Centaurus) thirty-seven stars, but in reality there are only thirty-six, the thirtieth is wanting." The star is No. 964 of Baily's edition of Ptolemy's Catalogue, and is rated γ, the twenty-ninth star immediately preceding (ε Centauri) being called β. From Ptolemy's longitudes and latitudes we find that the thirtieth star followed the twenty-ninth 0° 34′ in R.A. and 1° 10′ to the south of it. Q Centauri follows ε 26′·5, and is south 1° 5′·7; it is estimated 5·7 m. in Gould's *Uranometria*, but is a double-star, the components 6½ and 7½. Notwithstanding the difference in brightness, the approximate agreement of positions seems to point to Q Centauri as Ptolemy's thirtieth star.

OBSERVATIONS ON A GREEN SUN, AND ASSOCIATED PHENOMENA[1]

THE rarity of the phenomenon of a green or blue sun makes it desirable to record with the greatest accuracy and detail the observations made during its appearance in India during several days of September 1883.

The notes taken at Madras at the time of the appearance will best illustrate the general features of the phenomena :—

On September 9, the sun, before setting, assumed a peculiar silvery appearance, and its brightness was so much decreased that for about half an hour before sunset it could be observed with the naked eye. This was observed, I believe, though to a less extent, on the two days preceding, but I did not myself see it on these days. On September 10, from 5 to 5.30 p.m., the sun could easily be looked at with the naked eye, yet the limbs were sharply defined. At 5.30 the sun entered a low bank of clouds, and did not fully appear again ; but a narrow strip seen through a rift in the cloud at 5.43 was coloured a bright pea-green. Round Madras this colour had been seen in the morning, but in Madras itself clouds concealed the sun till it had risen to a considerable altitude. Of the morning of the 11th I have no record, but in the evening the green colour was brilliant, and was visible for more than half an hour, being preceded, as on the former night, by the silvery white appearance of the sun's disk. On this evening a large sunspot about 1' long was so conspicuous an object that it attracted the attention of even the most casual observers.

September 12.—At 12.35 a.m. the moon, which was near the horizon, appeared a pale green. Bright stars near the horizon showed the same tint. From 5.15 to 5.30 the clouds to the east were coloured reddish brown. At 5.55 the sun rose with a yellowish green colour, but was almost instantly lost in clouds. It reappeared at 6·4, and was then of a bright green colour: this colour rapidly got fainter, but was quite perceptible till 7 o'clock. In the afternoon the phenomena of the previous nights were repeated, and, the horizon being free from clouds, the actual sunset was observed. The entry in my notes is: "6.3.—The sun set as a greenish yellow ball; cumulus, stratus, and nimbus clouds near the horizon, but moon fairly clear ; some blue sky, but hazy." The change from green to greenish yellow was evidently due to the great increase in the strength of the low-sun-band close to the horizon, which left the strip of yellow between that band and the rain-band by far the most prominent feature in the spectrum.

September 13.—In the early morning there was a good deal of distant lightning. The sun rose of a bright, golden yellow colour ; no green was seen. In the afternoon there were slight showers.

A most remarkable observation made this morning by Mr. Pogson seems very difficult to explain, except by some form of auroral display. I give his notes in full :—

"1883, September 12, 17h. 0m. Madras mean time.—The sky a most remarkably intense reddish yellow, unusually bright. A dark cloud-bank from about east to south, and the vivid light above uncommonly auroral in appearance, more so than anything I have seen here before.

"At 17h. 10m. the red hue considerably diminished, and bright orange yellow the prevailing tint. The light quite bright enough to make notes by.

"At 17h. 20m. the dark blue-black stratum, now from about north to east, and very near the horizon. Sky tolerably clear to about 20° altitude, but of a rich red tint, with bright yellow clouds above, beginning at about 30°, and covering the rest of the sky.

"At 17h. 30m. all changed within the last four or five minutes, and writing now difficult without a lamp; a thick dark red stratum over the sunrise point, and everywhere else a very greenish yellow.

"At 17h. 40m. the low cloud stratum now sea-green. Light only enough to write by with difficulty.

"At 17h. 50m., sun rising a bright yellowish white, and otherwise nothing extraordinary, all unusual tints having disappeared with the sunrise."

September 14.—Before sunrise the clouds were blue and gray, with patches of red clouds of all sorts—cirrus, nimbus, stratus, cumulus, and mares' tails. Two bright flashes of lightning about 5.30 a.m. In the evening there was a slight green tinge, and after sunset the sky was golden red till 6.50, while Mercury, seen through the red haze, was twinkling strongly.

September 15.—The sun rose golden. In the evening the sunset was very fine: in the west the colour was golden to orange-yellow, in the east it was greenish ; red clouds remained till 7.5. There were very brilliant red "rayons de crépuscule."

From September 15 to September 20 the sunrises and sunsets were very fine, with red and gold, for more than half an hour before sunrise and after sunset.

September 21.—Sunset normal.

September 22.—The sun rose as a yellow ball, and showed distinct greenish yellow afterwards. From ten minutes before till sunset the sun was greenish yellow, but the sun was much brighter than on the 10th and 11th.

September 23.—The sun rose very green. At 5.37 p.m. the sun appeared from under clouds, very green ; strong absorption in the red end of the spectrum to C ; low-sun-bands weak. 5.45.—Clouds grayish purple. There was only one bank of clouds which was near the horizon ; above this was a peculiar grayish haze. At 6 the clouds were of a marked purple colour ; breaks near the horizon were reddish brown. During the night there was a great deal of sheet-lightning in the south.

September 24.—The sun rose bright yellow. The spectrum showed complete absorption up to B ; the rain-band a and β were very thick, and the low-sun-bands less marked than usual. There was lightning all night, beginning in the south, and working round to the south-east. It consisted chiefly of sheet-lightning, with occasional zig-zag flashes, but no thunder ; the stars were fairly clear except near the horizon. Saturn and the moon, when near the horizon, were both very dim.

September 25.—Sunrise golden green. In the afternoon the shadows cast on white paper were still quite pink, but the sunset was bright yellow.

September 26.—Much the same as yesterday.

September 27.—Before sunrise C, β, a, the rain-band and the dry-air-band were very strong, but the dry-air-band was less than half as dark as the rain-band. The sun rose golden red. The spectrum showed signs of clearing up ; glimpses of A could be obtained. After dark there was very bright lightning in the west.

September 28.—Spectrum still showed great absorption. Lightning at night.

September 29.—Spectrum absorption still very strong. After dark there was a display of luminous clouds specially towards the east. After 11 p.m. there was very heavy rain with much lightning and some thunder.

September 30.—Sunrise golden. The spectrum *on* the sun showed A clearly, a was very thick.

October 2.—In the morning from about 7 to 9 there was a thunderstorm, in which the thunder was almost continuous for about an hour and a half, but although the storm was almost vertically overhead, hardly any lightning was visible. . . . The total rainfall for the day was 4·88 inches.

Accounts were collected from trustworthy observers in various parts of India. All describe the brilliant sunsets of the first week of September, and record the appearance of a green sun on several days. It was seen at Muttum in the south of Madras on the 9th, and continued for several days both in the morning and the evening. The green colour was then lost, but reappeared from the 22nd to the 28th inclusive.

At Bellary the sun was seen "emerald-green" at rising and setting from the 10th to the 14th inclusive. The observations were not carried on longer.

At Coonoor on the Nilgiris the abundance of green tints in the sunsets was noted, but the sun itself was merely described as of a "shimmery" appearance.

The observations at Ongole have been already noticed in NATURE.

The Spectrum.—The spectrum of the sun when green was repeatedly observed and photographed with the large zodiacal-light spectroscope, which is furnished with one large prism of dense glass and a very long collimator permitting the use of a wide slit. The main features of the spectrum taken *on* the sun when green were—

1. A very strong general absorption in the red end.
2. A great development of the rain-band and of all other lines that are ascribed to the presence of water-vapour in the atmosphere, more especially of the group C_1 of a and of the band at W.L. 504.

The absorption in the red end was of very varying intensity,

[1] Abstract of a paper read before the Royal Society of Edinburgh, July 7, by Prof. C. Michie Smith.

but when the phenomenon was at its maximum phase it gradually crept up from about B till past C, as the sun sank towards the horizon. On the 12th, when the sun was within a few degrees of the horizon, the absorption was well marked up to W.L. 621, *i.e.* to beyond *a*, while at the violet end the visible spectrum ended at W.L. 428, or just beyond G.

The lines A and *a* were never visible even *on* the sun, when it was green, and even B could be made out with difficulty from half an hour before sunset onwards, and before it vanished it grew intensely prominent with enormously thick bands on the less refrangible side. The band C_1 on the more refrangible side of C became very broad and black, while the fine line between this and C remained thin and sharp, and C itself thickened out on the less refrangible side. The rain-band was stronger than I have ever before observed it on the plains, and even with the dispersion produced by a single prism at least eight lines could be measured in it, while many more were visible. The low-sun-band was not very conspicuous, but this was partly due to contrast with the very strong rain-band. The line W.L. 568 at the more refrangible side of the low-sun-band was very well marked, and the band itself seemed to consist of a series of equidistant lines.

The apparently much stronger absorption in the red than in the blue end was a very marked feature, which became still more conspicuous when a photograph of the blue end was examined.

Since the passing away of the abnormal conditions I have made careful observations of the sunset spectrum with the same apparatus, and I find that ordinarily A and *a* are clearly visible as well as B, though at times they are strongly marked, and a good deal of shading is observable between them; C_1 is much thinner, and the rain-band is less prominent than the low-sun-band, which however does not now have the appearance of a number of fine lines. The nearest approach to the green-sun spectrum was observed recently during a severe thunderstorm, which was accompanied by a fall of about 1½ inches of rain. A very similar though less intense spectrum can be observed almost any evening by taking advantage of the passage of a small thin cloud over the sun's disk. If a lens is used in front of the slit of the spectroscope, the absorption due to the cloud will be seen as a band in the middle of the bright spectrum from the unclouded part of the sun, and owing to the strong contrast, the details of the absorption will be well seen, just as in the case of the spectrum of a sunspot.

Meteorological Phenomena.—The electrification of the air was carefully studied during the green sun period, and the results are rather curious. From September 3 to 6 the potential of the air was positive in the early morning, diminished to zero between 9 and 10 a.m., then became negative, and remained so until the sea-breeze came on in the afternoon, when the charge was positive again, and continued so all night. The amount of electrification varied greatly and rapidly. On the 7th and 9th the potential was positive all day, on the 8th it was negative for a short time. From the 10th to the 12th it varied in the same way as from the 3rd to the 6th, and this state of matters was repeated from the 20th to the 27th; the electrometer readings from the 13th to the 19th having been normal. All the negative readings were got during a hot land wind from the west. Between the 6th and 9th of September a storm of unusual violence swept over the Madras Presidency from the south-west to the north-east, making itself felt in different ways at different places. The rainfall for September was unusually small all over Madras. The average for fifteen stations was 3·24 inches, not quite half the average for this month during previous years.

The barometric curves for Colombo, Madras, Belgaum, Allahabad, and Calcutta (Alipore) have been drawn and found to resemble each other closely. All over India there was a minimum between the 6th and the 7th, a maximum about the 18th, another minimum on the 21st, then a rise, and a third minimum on the 27th.

The first essential in any attempt to arrive at an explanation of the cause of the green sun is to ascertain the precise dates at which the phenomenon was first observed in various parts of the world. It is difficult to do this, for people are apt to make more precise statements than their observations warrant. For instance, the sun certainly set with a peculiar silvery gleam, but no greenness, at Madras on September 9, and yet many persons have assured me that they saw it set green there on that evening. The reason evidently was that after their attention had been arrested by the green sunsets of the 10th and 11th they remembered having noticed something peculiar about the sunset on the 9th, and immediately concluded that the sun had been green on that occasion also. In consequence of this tendency of the mind, the evidence for all the dates given has been carefully tested, and has been found in all cases sufficient to justify the opinion that these dates are correct.

It appears that in Ceylon, in the south part of the Madras Presidency, and at Ongole in the north, the sun was first observed to be green on the evening of the 9th, and that over the east of the Presidency, when seen at all, it was first seen green on the morning of the 10th. The green sun was reported at Belgaum on the 8th, but although the observer was trustworthy, he did not make a note of the fact until afterwards, and it is just possible that it may be a mistake.

The captain of the *Cleomene* reports a green sun and moon on the 9th, 10th, and 11th, when his position was from lat. 8° N. to lat. 16° N., and from long. 83° 30′ E. to long. 88° 40′ E. The chief officer of the s.s. *Pelican* saw the moon greenish on the night of the 9th, and the sun green on the morning of the 10th. The steamer was more than 1000 miles away from Madras, in lat. 10° 4′ N. and long. 64° 12′ E., wind south-west.

The green sun was not seen further north than Ongole, except at Vizagapatam, Rajamundry, and Simla, and the dates of observation at these stations are not preserved. It was seen at Bombay, but was so inconspicuous that it escaped notice at the Observatory.

In Honolulu the sun's disk was seen to be green before it set on September 4 and 5 (NATURE, vol. xxix. p. 549). On September 4 the master of the *Jennie Walker* "noticed the strange appearance of the sun, which was greenish," in lat. 8° 20′ N. and long. 155° 28′ W. A passenger three days out from Honolulu for Sydney saw it blue on the 5th and 6th (*Ibid.*, p. 181). On September 2 it was observed bluish green in Venezuela and in Trinidad (*Ibid.*, vol. xxviii. p. 577, vol. xxix. p. 77). It was seen at Panama on the 2nd and 3rd, and at Cape Coast Castle apparently on the 1st of September. So much for the first appearance.

The sun was again seen green on September 20, in lat. 12° 50′ N. and long. 48° 26′ E. At almost all stations in Southern India the greenness reappeared on the 22nd, and Hicks Pasha noticed the sun green in the Soudan on the 24th.

The phenomena of the green sun must be distinguished from those of the remarkable sunsets that occurred all over the world some time later, and the reasons for considering them essentially different are:—

1. The general appearances of the sunsets were quite different. The sunsets accompanying the green sun were lurid, and the horizon so misty that stars were lost in it; the subsequent sunsets were remarkable for the play of delicate tints, the rose-coloured after-glow, and the unusual clearness of the horizon.

2. The spectra were totally different. In the latter case the red end was unusually free from absorption; A, a, and B stood out clearly, the rain-band was slight, and the low-sun-bands strong. This contrasts in every way with the description of the spectrum of the green sun already given.

Three hypotheses have been put forward to account for the phenomena of the green sun:—

1. That it was due to vapours or dust from the volcanic eruption at Krakatao. This was at first proposed by Mr. Pogson.

2. That the cause was the presence of an abnormal amount of aqueous vapour—an explanation which I offered at the time of the occurrence.

3. That it was caused by a cloud of meteoric dust.

The supporters of the Krakatao theory view the phenomena of the green sun and the remarkable sunsets as due to the same cause. The two great difficulties with regard to that hypothesis are (1) that there is no proof of the existence of an air current travelling at the enormous velocity required by the dates of the appearances of the green sun at various places, and (2) granting that there was such a current, how it was that the dust was such a long time in reaching India. Mr. Lockyer gets over these difficulties by assuming the existence of an upper current from east to west along the equator, and an under current from south to north. If, however, Mr. Manley's observations are accurate, as there seems every reason to believe they are, the green sun appeared at Ongole as soon as in Colombo, and at least twelve hours sooner than in Madras; and, if the Belgaum observations are correct, it appeared there a day before it was noticed at Colombo. Taking, however, only those observations about

which there can be no doubt, we get the following velocities, taking the shortest lines between Krakatao and the various stations :—

To Colombo	2000 miles,	6·7 miles per hour
,, Madras	2240 ,,	7·3 ,, ,,
,, Bellary	2450 ,,	7·9 ,, ,,
Lat. 10° 4′ N., long. 64° 12′ E.	3100 ,,	9·8 ,, ,,

These required velocities increase with the distance, and, taking along with them the rate of forty miles an hour demanded by the Japan observations, it is difficult to believe that dust could have travelled in these various directions with such different velocities.

There is also the negative evidence that rain-water collected in Madras during the period of the green sun contained no volcanic dust, as far as a careful microscopic examination of the residue could determine it. On the dust hypothesis, too, it is difficult to understand the cessation and reappearance of the phenomenon.

There is some definite evidence on which to base the argument for the water-vapour theory. The observations detailed at the beginning of this paper show that the spectrum of the green sun had the absorption-lines of water-vapour very well marked, and that there was also a general absorption in the red. This absorption might indeed be accounted for by supposing a number of dust particles of a certain size to be suspended in the air; but a precisely similar absorption has been observed when the sunlight traversed the very thick clouds of a violent thunderstorm. The fact that water-vapour may make the sun appear green is proved by the numerous observations of a green sun through the escaping vapour from the funnel of a steamer, and through mist. The abundance of water-vapour in suspension was proved by the very heavy monsoonal rains which followed the appearance of the green sun. In Madras the rainfall was 19·17 inches above the average.

The green sun, although uncommon, is by no means so rare a phenomenon as is generally supposed. Since my attention has been directed to it, I have observed it several times, very conspicuously on May 13 and 14. But there is a reason why it should not appear much more frequently, and that is that, supposing the absorption producing it to be brought about by an abnormal amount of water-vapour, that vapour must be in suspension, while in fact it generally partly precipitates, forming clouds that conceal the sun as its hour of setting approaches. An interesting question arises as to whether the clearness of the atmosphere, when a large amount of aqueous vapour was in suspension during the appearance of the green sun, might not be due to an abnormal electrical state. The numerous and intense thunderstorms that occurred during the period showed that all the clouds were highly electrified, and the electrometer observations already referred to also indicated an unusually electrified atmosphere; but I am not prepared to lay much stress on the electrometer readings until I have made a more extended series of observations in ordinary weather.

The presence of abundance of aqueous vapour at the time of the appearance of the green sun may be explained naturally enough by the setting in of the moist monsoon currents in the upper parts of the atmosphere, or at least by the conflict between the north-east and south-west monsoons, which had commenced by that time.

It is not at all improbable that the Krakatao eruption had some influence on the direction of these currents. The ejection of a large volume of heated vapour would produce a centre of low pressure and set up a cyclonic influx of air from other places. It is possible that the peculiarities observed in the Indian barometric curves for some time after the eruptions were due to this cause. The eruption, too, might have something to do with the electrical conditions; for it is known from Prof. Palmieri's observations that electricity is generated by the eruptions of Vesuvius.

I was once inclined to view with favour the theory of the appearances being produced by cosmic dust, supposing the dust to act either by its mere presence or by forming nuclei for absorption; but considerations of the amount of solar radiation during the greenness have shaken my faith in this explanation.

We must, therefore, I think, give up any theory involving the presence of sufficient dust to render the sun green. Whether or not the following sunset glows were due to dust I cannot discuss here; but I would point out that an amount of dust sufficient to produce these effects would probably not materially affect the transparency of the atmosphere.

EDUCATION, SCIENCE, AND ART

THE Select Committee of the House of Commons appointed to consider how the Ministerial responsibility under which the votes for Education, Science, and Art are administered may be best secured, have agreed to the following report :—

Your Committee have examined the present and several former Presidents and Vice-Presidents of the Council, Secretaries to the Lord Lieutenant of Ireland, permanent heads of the Education Department in London, the present Resident Commissioner of National Education in Ireland, and also other gentlemen conversant with the matters referred to your Committee. They have also considered the evidence taken before the Select Committee appointed in 1865 and 1866 to inquire into the constitution of the Committee of Council on Education.

The first question considered by your Committee was whether primary education in Great Britain and in Ireland should be placed under one supervising Minister. Your Committee are satisfied that under present circumstances it would be undesirable to disturb the existing arrangements as to the Ministerial responsibility for primary education in Ireland.

They are also of opinion that primary education in England and Scotland should be under the control of the same Minister.

The Lord President of the Council, almost always a peer, is nominally the head of the Education Department for Great Britain.

The Vice-President represents the department in the House of Commons, and really transacts almost all the business requiring authority above that of the permanent officials.

Your Committee are of opinion that this arrangement is neither logical nor convenient. They see no sufficient reason why there should be any more real connection between the Education Department and the Privy Council than between the Board of Trade and the Privy Council; but as it may be convenient that the Minister for Education should have occasionally the assistance, whether as to English or Scotch Education, of other Privy Councillors specially summoned for consultation with him, they recommend that a Board of (or Committee of Council for) Education should be constituted under a President, who should be the real as well as nominal Minister, in this respect holding a position like that of the President of the Board of Trade. Hitherto there has been a separate Scotch Department of the Privy Council, and your Committee consider that it would be well to have a distinct permanent secretary appointed for Scotland, responsible to the Minister of Education.

Whether the Minister of Education should always be a member of the Cabinet or of the House of Commons, and what should be his salary, are questions upon which it is hardly within the province of your Committee to make absolute recommendations. They think, however, that the duties of this Minister should be recognised as not less important than those of some of the Secretaries of State.

The Minister of Education should have the assistance of a Parliamentary Secretary, able to sit in either House of Parliament.

While on the whole preferring the plan they have suggested, your Committee do not deny that there are objections to the constitution of an administrative department in the form of a board which has no real existence. The permanent secretary and his assistants bind by their signature, nominally the board, really, the political chief.

This system, it must be admitted, tends to lessen the direct control and responsibility to Parliament and the public which is apparent in the office of a Secretary of State.

The second question discussed by your Committee was whether, and if so what, authority should be exercised by the Minister of Education over endowed schools. Your Committee recommend that when schemes for endowed schools, whether in England or in Scotland, have come into operation, the Minister of Education should have full authority to call on the governing bodies to furnish him with such reports and information as he may require, and to direct any inquiries or inspection to be made which he may deem necessary.

As to public schools, your Committee recommend that the Minister of Education should be authorised to call for such reports and information as he may require from the governing bodies, but they are not of opinion that his powers should extend to directing inspection.

With respect to the Universities in Great Britain receiving grants charged on the votes of Parliament or on the Consolidated

Fund, the Minister should be authorised to require from them an annual report in such form as he may order.

Your Committee have not taken any evidence as to reformatory and industrial schools, considering that these have so recently formed the subject of an inquiry by a Royal Commission, the report and recommendations of which are before Parliament. They see no reason for altering the present responsibility for workhouse schools or for the primary schools connected with the Army, the Navy, or the Marines. The responsibility for the administration of the votes for military and naval colleges do not appear to come within the reference to your Committee.

Your Committee see no reason to disturb the existing arrangements as to the supervision of the Science and Art Department.

There are various miscellaneous votes for science and art, such as those for scientific research, distributed through the Royal Society, votes for meteorology, and votes in aid of the Royal Society of Edinburgh and the Royal Irish Academy. These votes, your Committee think, should be moved by the Minister of Education, and reports, when necessary, should be made to him.

Your Committee do not propose to bring the British Museum and the National Gallery into closer relations with Her Majesty's Government than those now existing, with this exception, that, in their opinion, the Minister of Education and the Parliamentary Secretary should be *ex officio* trustees of each of those institutions. The President of the Council, your Committee notice, is now an *ex officio* trustee of the British Museum. The House of Commons would then look to the Education Department for explanations when the votes for the British Museum and the National Gallery are discussed in Committee of Supply.

The Committee, of which the Chancellor of the Exchequer was chairman, included, among other members, Sir J. Lubbock, Mr. Salt, Mr. Raikes, Sir L. Playfair, Mr. S. Morley, Mr. Pell, Mr. Sclater-Booth, and Mr. J. Collings.

THE MARINE BIOLOGICAL ASSOCIATION

THE Council of the Marine Biological Association adopted the following statements at its meeting held on July 25 last:—

MEMORANDUM No. I.

The Marine Biological Association was founded in March, 1884, at a meeting held in the apartments of the Royal Society of London, Prof. Huxley, P.R.S., in the chair. Its officers and council include the leading naturalists of the country, as well as noblemen and others who took an active part in the late Fisheries Exhibition. H.R.H. the Prince of Wales has consented to be Patron of the Association, and has given evidence of the importance which he attaches to the success of its objects by contributing a handsome donation to its funds. The following is a list of the Executive of the Association:—

President: Prof. Huxley (President of the Royal Society).

Vice-Presidents: The Duke of Argyll, K.G.; the Duke of Sutherland, K.G.; the Marquis of Hamilton; the Earl of Dalhousie, K.T.; Lord Walsingham (Trustee of the British Museum of Natural History); Prof. Allmann, F.R.S.; Sir John St. Aubyn, Bart., M.P.; Edward Birkbeck, M.P. (Chairman of the Executive Committee of the International Fisheries Exhibition); George Busk, F.R.S.; W. B. Carpenter, C.B., M.D., F.R.S.; W. H. Flower (Director of the British Museum of Natural History); J. Gwyn Jeffreys, F.R.S.; Sir John Lubbock, Bart., M.P. (President of the Linnean Society).

Council: Prof. Moseley, F.R.S. (Oxford), Chairman; C. Spence Bate, F.R.S. (Plymouth); Prof. Jeffrey Bell, F.Z.S. (British Museum); W. S. Caine, M.P.; W. T. Thiselton Dyer, C.M.G., F.R.S. (Royal Gardens, Kew); John Evans, D.C.L. (Treasurer, R.S.); A. C. L. G. Günther, F.R.S. (British Museum); Prof. Herdman (Liverpool); E. W. H. Holdsworth; Prof. McIntosh (St. Andrew's); Prof. Milnes Marshall (Manchester); Sir Philip Cunliffe Owen, K.C.M.G., C.B.; G. J. Romanes, F.R.S. (Secretary of the Linnean Society); P. L. Sclater, F.R.S. (Secretary of the Zoological Society); Adam Sedgwick (Cambridge).

Hon. Treasurer: Frank Crisp (Vice-President and Treasurer of the Linnean Society), 6, Old Jewry, E.C.

Hon. Secretary: Prof. E. Ray Lankester, F.R.S., 11, Wellington Mansions, North Bank, N.W.

The object of the Association is to erect one or more laboratories on the coast of the United Kingdom, where studies may be carried on by naturalists, leading to an improvement in zoological and botanical science, and especially to an adequate acquaintance with the food, habits, spawning, and propagation of our marine food-fishes and shell-fish.

Great scientific and practical results have been obtained in other countries, notably in the United States of America, in Germany, France, and Italy, by studies carried on through such laboratories as the Marine Biological Association proposes to erect in this country. The knowledge which can be thus and thus only gained is precisely that knowledge which is at present *urgently* needed in order to regulate and improve British Sea Fisheries, and it therefore seems to be not inappropriate that public bodies as well as individuals interested in the progress of natural history science should take in hand the promotion of the first attempt to institute an efficient sea-coast laboratory in these islands.

It is estimated by the Council that a sum of 10,000*l.* will be required to build and equip an efficient laboratory, and to insure a successful start for the Association. This sum does not include any payment to the naturalists who may conduct the operations of the laboratory, since in the first instance, at any rate, such services will be rendered gratuitously. The money which is now asked for will be expended entirely upon the laboratory, its equipment, and necessary service.

As the result of an appeal to scientific men and their immediate friends the Association has raised a sum of about 2000*l.* In order to obtain the rest of the money which is required it is necessary to appeal to a wider circle.

The Council of the Association feel that they have undertaken a work of national importance, and therefore confidently appeal to those who have pecuniary resources at their disposal to give them substantial aid in its realisation.

According to the bye-laws of the Association adopted at a meeting of members on June 17, 1884, donors of 500*l.* to the Association become governors and permanent members of the Council of the Association. The Council hope that they may receive some contributions of this amount or of larger sums, and would suggest that it might be found convenient by those who may intend to assign sums of large amount to the Association to do so in the form of a payment of so much a year spread over a term of years.

The donor of 100*l.* to the Association becomes a "Founder" and life-member. An annual subscription of 1*l.* 1*s.*, or a composition fee of 15*l.* 15*s.*, is required of ordinary members. Members of the Association have the right to take part in the government of the Association by electing the Officers and Council at their annual meeting: they will receive the printed reports of the Association, and enjoy special privileges in the use of the laboratory and its resources.

It is intended to require an entrance fee of 5*l.* 5*s.* from members who join the Association later than June, 1885.

Signed (on behalf of the Council of the Marine Biological Association),
H. N. MOSELEY, M.A., F.R.S.,
Chairman of the Council,
Linacre Professor of Anatomy in the University of Oxford
July 25, 1884

MEMORANDUM NO. II.—*Nature of the Building, Management, and Work of the Proposed Marine Laboratory and Experimental Aquarium.*—The Council of the Marine Biological Association cannot as yet definitely pledge itself as to details, but the following is a sketch of the nature of the building which it proposes to erect, of the probable management of the Laboratory, and of the kind of work which may be expected to be accomplished by its aid.

The most complete institution of the kind is that at Naples, which is supported by contributions from various European States, and is especially subsidised by the German Imperial Government. The buildings, fittings, and boats belonging to this institution have cost 20,000*l.* It is proposed to *start* such an institution in this country with half this sum.

1. *Building.*—The first laboratory of the Marine Biological Association will probably be erected on the shore of Plymouth Sound. Plymouth is not only by its natural features one of the best possible localities for the purpose, but a Committee of the Town Council has offered to the Association a suitable site free of cost and a contribution of 1000*l.*

With regard to the building, the Council of the Marine Biological Association contemplate erecting a solid brick structure

of about 100 × 40 feet ground area, and of two stories. The exterior will be simple and unpretentious. The building will be placed close to the sea-shore, so that sea water can be readily pumped into the laboratory tank, and in order that there may be easy communication with fishing-boats. It will also be desirable to have a floating barge anchored near the laboratory for special experiments on the breeding of fish, &c., and, in close proximity, it will be necessary to erect tanks on the foreshore, open to the tidal water, but arranged so as to prevent the escape of the animals confined in them for study.

The basement of the building will contain a reservoir tank holding several thousand gallons of sea water; on the ground floor there will be two large rooms paved with stone; one fitted with large tanks and a service of sea water, the other used for the reception and examination of a day's trawling or dredging, and also used for keeping stores and for carrying out the pickling and proper preservation of specimens to be sent, as required, to naturalists at a distance. The upper floor will be divided into a series of larger and smaller working rooms fitted with suitable tables, with reagents and apparatus required in microscopy, and with a constant supply of sea water pumped from the reservoir tank. Accommodation for ten workers will be thus provided. One of the rooms on this floor must be set apart as a library and writing-room, and must contain as complete a series of works on marine zoology and botany, pisciculture, and such matters as can be brought together. The provision of such a library is one of the special conveniences which would be offered to naturalists working in the laboratory.

The building must also necessarily contain bed-room and sitting-room for a resident superintendent, and accommodation for one servant or caretaker.

2. *Apparatus and Boats.*—These need not at first be very extensive. Glass tanks, pumping engine and supply tubes are essential. There will be necessarily one small steam-launch for dredging in quiet weather at no great distance from shore, and a row-boat. For special expeditions larger boats or steamers could be either hired or borrowed from time to time. The local fishermen would also greatly aid the laboratory if regularly paid, and thus supplement the special boats of the Association.

3. *Salaried Staff.*—The Council would propose to begin work with the smallest possible number of permanent *employés*. These would be—(*a*) a resident superintendent, who should be a man of fair education and some knowledge of natural history, at a salary of 150*l*. a year, supplemented by free quarters; (*b*) a servant of the fisherman class, who would look after the tanks and workrooms, go out in search of specimens, and manage a boat and dredging apparatus when required. Other fishermen and boys might be hired from time to time. A sum of 100*l*. a year would be required for such service at the least.

4. *Conditions of Admission to Use of Laboratory: Work to be done there.*—The Council would propose to admit to the use of a table and other resources of the laboratory, so far as the space shall permit, any British or foreign naturalist who might make application and furnish evidence of his capability to make good use of the opportunities of the place. A preference would be given to a member of the Association. A fee might in some cases be charged for the use of a table, and other tables might be let out at an annual rental to such bodies as the Universities, this being the system adopted at Naples by Dr. Dohrn.

The Council will endeavour, when the laboratory is erected and in operation, to obtain grants of money from scientific societies, and from the Government, for the purpose of carrying out *special* investigations on a given subject, *e.g.*, the conditions affecting the fall of oyster-spat, the reproduction and general economy of the common sole, the complete determination and enumeration of the fauna and flora of the marine area adjacent to the site of the laboratory, its distribution within that area, and its relation to physical conditions. Naturalists will be nominated by the Council of the Association or by the authorities who find the money by which such naturalists are paid, to make such researches at the laboratory of the Association. When some special investigation is thus started at the laboratory, the other naturalists, who from time to time come there, will be sure to take part in the inquiry, and so help to carry it on to completion. It would be the business of the resident superintendent to facilitate this continuity of work, whilst the Council of the Association will make it a special object to bring together the results attained in the laboratory each year, in the form of a report, so as to gradually organise and direct towards definite ends the work done through its agency.

In the course of time, and with increased provision of funds for the special purpose, the Association might expect to be the means of producing—

1. A thorough knowledge of the life and conditions of the marine area adjacent to the laboratory.
2. A complete and detailed account of the natural history of certain fishes, molluscs, and crustaceans of economic importance with special reference to their increased supply.
3. Contributions to the knowledge of the growth from the egg, adult structure and physiology of such rare or otherwise scientificially interesting animals and plants as occur near the laboratory.

It is not supposed that this can be immediately accomplished by the 10,000*l*. which the Association now seeks to raise. That sum will be expended in erecting the laboratory and in starting it on its career of activity. The laboratory will necessarily attract support and increased means of usefulness as, year by year, its work becomes known, and the facilities which its offers to working naturalists appreciated.

Signed (by order of the Council of the
Marine Biological Association),

E. RAY LANKESTER, M.A., F.R.S.,
Hon. Secretary

July 25

THE METEOROLOGICAL CONFERENCE

A METEOROLOGICAL conference was held at the Health Exhibition on July 17 and 18; the following is an abstract of the leading papers read at the conference.

Dr. J. W. Tripe read a paper of much interest on some relations of meteorological phenomena to health.

In ages long past these relations excited much attention, but the knowledge concerning them was of the vaguest kind; and indeed, even now, no very great advance has been made, because it is only quite recently that we have been able to compare a fairly accurate record of deaths with observations taken at a number of reliable meteorological stations. The more useful and searching comparison between cases of sickness, instead of deaths, and meteorological phenomena has yet to be accomplished on a large scale in this country, and especially as regards zymotic diseases. In Belgium there is a Society of Medical Practitioners, embracing nearly the whole country, that publishes a monthly record of cases of sickness, of deaths, and of meteorological observations; but the only attempt on a large scale in this country, which was started by the Society of Medical Officers of Health for the whole of London, failed partly from want of funds, and partly from irregularity in the returns. My remarks, which must necessarily be very brief, will refer to the relations between (1) meteorological phenomena and the bodily functions of man, and (2) between varying meteorological conditions and death-rates from certain diseases.

As regards the first, I will commence with a few brief remarks on the effects of varying barometric pressures. A great deal too much attention is paid to the barometer if we regard it as indicating only, as it really does, variations in the weight of the column of air pressing upon our bodies, because, except at considerable elevations, where the barometer is always much lower than at sea level, these variations produce but little effect on health. At considerable elevations the diminished pressure frequently causes a great feeling of malaise, giddiness, loss of strength, palpitation, and even nausea; and at greater heights, as was noticed by Mr. Glaisher in a very lofty balloon ascent, loss of sight, feeling, and consciousness. These were caused by want of a sufficient supply of oxygen to remove effete matters from the system, and to carry on the organic functions necessary for the maintenance of life. On elevated mountain plateaus, or even in high residences amongst the Alps, an increased rapidity in the number of respirations and of the pulse, as well as increased evaporation from the lungs and skin, occur.

For some years past, many persons suffering from consumption, gout, rheumatism, and anæmic affections have gone to mountain stations, chiefly in Switzerland, for relief, and many have derived much benefit from the change. It must not however, be supposed that diminished atmospheric pressure was the chief cause of the improvement in health, as its concomitants, viz., a diminution in the quantity of oxygen and moisture contained in each cubic foot of air, probably the low temperature, with a

total change in the daily habits of life, have assisted in the beneficial results. The diminution in the quantity of air, and consequently of oxygen, taken in at each breath is to a certain extent counterbalanced by an increased frequency and depth of the respirations, and a greater capacity of the chest. In this country, alterations in the barometric pressure are chiefly valuable as indicating an approaching change in the wind, and as well as of the amount of moisture in the air; hence the instrument is often called "the weather glass." A sudden diminution in the atmospheric pressure is likely to be attended with an escape of ground air from the soil, and therefore to cause injury to health, especially amongst the occupants of basement rooms, unless the whole interior of the building be covered with concrete.

Temperature.—Experience has shown that man can bear greater variations of temperature than any other animal, as in the Arctic regions a temperature of 70 degrees Fahrenheit, or more than 100 degrees below freezing-point, can be safely borne; that he can not only live but work, and remain in good health in these regions, provided that he be supplied with suitable clothing and plenty of proper food. On the other hand, man has existed and taken exercise in the interior of Australia, when the thermometer showed a temperature of 120 degrees Fahrenheit, or nearly 90 degrees above freezing-point, so that he can live and be in fairly good health within a range of nearly 200 degrees Fahrenheit.

The effects of a high temperature vary very much according to the amount of moisture in the air, as when the air is nearly saturated in hot climates, or even in summer in our own, more or less languor and malaise are felt, with great indisposition to bodily labour. With a dry air these are not so noticeable. The cause is evident; in the former case but little evaporation occurs from the skin, and the normal amount of moisture is not given off from the lungs, so that the body is not cooled down to such an extent as by dry air. Sunstroke is probably the result, not only of the direct action of the sun's rays, but partly from diminished cooling of the blood by want of evaporation from the lungs and skin.

The effects of temperature on man does not depend so much on the mean for the day, month, or year, as on the extremes, as when the days are hot and the nights comparatively cool, the energy of the system becomes partially restored, so that a residence near the sea, or in the vicinity of high mountains, in hot climates is, other things being equal, less enervating than in the plains, as the night air is generally cooler. It is commonly believed that hot climates are *necessarily* injurious to Europeans, by causing frequent liver derangements and diseases, dysentery, cholera, and fevers. This, however, is, to a certain extent, a mistake, as the recent medical statistical returns of our army in India show that in the new barracks, with more careful supervision as regards diet and clothing, the sickness and death-rates are much reduced. Planters and others, who ride about a good deal, as a rule keep in fairly good health; but the children of Europeans certainly degenerate, and after two or three generations die out, unless they intermarry with natives, and make frequent visits to colder climates. This fact shows that hot climates, probably by interfering with the due performance of the various processes concerned in the formation and destruction of the bodily tissues, eventually sap the foundations of life amongst Europeans; but how far this result has been caused by bad habits as regards food, exercise, and self-indulgence, I cannot say. Rapid changes of temperature in this country are often very injurious to the young and old, causing diarrhœa and derangements of the liver when great heat occurs, and inflammatory diseases of the lungs, colds, &c., when the air becomes suddenly colder, even in summer.

The *Direct* influence of rain on man is not very marked in this country, except by giving moisture to the air by evaporation from the ground and from vegetable life, and by altering the level of ground water. This is a subject almost overlooked by the public, and it is therefore as well that it should be known that when ground water has a level, persistently less than five feet from the surface of the soil, the locality is usually unhealthy, and should not, if possible, be selected for a residence. Fluctuations in the level of ground water, especially if great and sudden, generally cause ill-health amongst the residents. Thus, Dr. Buchanan in his Reports to the Privy Council in 1866-67, showed that consumption (using the word in its most extended sense) is more prevalent in damp than on dry soils, and numerous reports of medical officers of health, and others, which have been published since then, show that an effective drainage of the land, and consequent carrying away of the ground water, has been followed by a diminution of these diseases.

Varying amounts of moisture in the air materially affect the health and comfort of man. In this country, however, it is not only the absolute but the relative proportions of aërial moisture which materially influence mankind. The quantity of aqueous vapour that a cubic foot of air can hold in suspension, when it is saturated, varies very much with the temperature. Thus at 40 degrees Fahr. it will hold 2·86 grains of water; at 50 degrees, 4·10 grains; at 60 degrees, 5·77 grains; at 70 degrees, 8·01 grains; and at 90 degrees as much as 14·85 grains. If saturation be represented by 100, more rapid evaporation from the skin will take place at 70 degrees, and 75 per cent. of saturation, than at 60 degrees when saturated, although the absolute quantity of moisture in the air is greater at the first-named temperature than at the latter. As regards the lungs, however, the case is different, as the air breathed out is, if the respirations be regular and fairly deep, completely saturated with moisture at the temperature of the body. In cold climates the amount of moisture and of the effete matters given off from the lungs in the expired air, is much greater than in hot climates, and the body is also cooled by the evaporation of water in the form of aqueous vapour. Moist air is a better conductor of heat than dry air, which accounts for much of the discomfort felt in winter when a thaw takes place as compared with the feeling of elasticity when the air is dry. In cold weather, therefore, moist air cools down the skin and lungs more rapidly than dry air, and colds consequently result. London fogs are injurious, not only on account of the various vapours given off by the combustion of coal, but in consequence of the air being in winter generally saturated with moisture at a low temperature. The injuriousness of fogs and low temperatures will be presently dwelt upon at greater length.

Variations in the pressure and temperature of the atmosphere exert a considerable influence on the circulation of air contained in the soil, which is called ground air. As all the interstices of the ground are filled with air or water, the more porous the soil, the greater is the bulk of air. The quantity of air contained in soil varies very much according to the material of which the soil is composed, as it is evident that in a gravelly or sandy soil it must be greater than when the ground consists of loam or clay. The estimates vary from 3 to 30 per cent., but the latter is probably too high. If, therefore, a cesspool leak into the ground, the offensive effluvia, if in large quantities, will escape into the soil, and are given off at the surface of the ground, or are drawn into a house by the fire; but, if small, they are rendered inocuous by oxidation. The distance to which injurious gases and suspended or dissolved organic matters may travel through a porous soil is sometimes considerable, as I have known it pass for 130 feet along a disused drain, and above 30 feet through loose soil.

Winds exercise a great effect on health both directly and indirectly. Directly, by promoting evaporation from the skin, and abstracting heat from the body in proportion to their dryness and rapidity of motion. Their indirect action is more important as the temperature and and pressure of the air depend to a great extent in their direction. Thus winds from the north in this country are usually concomitant with a high barometer and dry weather; in summer with a pleasant feeling, but in winter with much cold. South-west winds are the most frequent here of any, as about 24 per cent. of the winds come from this quarter against 16½ from the west, 11½ from the east, and the same from the north-east; 10½ from the south, 8 from the north, and a smaller number from the other quarters. South-west winds are also those which are most frequently accompanied by rain, as about 30 per cent. of the rainy days are coincident with south-west winds. Another set of observations give precisely the same order, but a considerable difference in their prevalence, viz. south-west 31 per cent., west 14½, and north-east 11½ per cent. Easterly winds are the most unpleasant, as well as the most injurious to man of all that occur in this country.

I now propose discussing very briefly the known relations between meteorological phenomena and disease. I say the known relations, because it is evident that there are many unknown relations of which at present we have had the merest glimpse. For instance, small-pox, while of an ordinary type, and producing only a comparatively small proportion of deaths to those attacked, will sometimes suddenly assume an epidemic form, and spread with great rapidity at a time of year and under the meteorological conditions when it usually declines in fre-

quency. There are, however, in this country known relations between the temperature and, I may say, almost all diseases. As far back as 1847 I began a series of elaborate investigations on the mortality from scarlet fever at different periods of the year, and the relations between this disease and the heat, moisture, and electricity of the air. I then showed that a mean monthly temperature below 44°·6 F. was adverse to the spread of this disease, that the greatest relative decrease took place when the mean temperature was below 40°, and that the greatest number of deaths occurred in the months having a mean temperature of between 45° and 57° F. Diseases of the lungs, excluding consumption, are fatal in proportion to the lowness of the temperature and the presence of excess of moisture and fog. Thus, in January 1882 the mean weekly temperature fell from 43°·9 F. in the second week to 36°·2 in the third, with fog and mist. The number of deaths registered in London during the third week, which may be taken as corresponding with the meteorological conditions of the second week, was 1700, and in the next week 1971. Unusual cold, with frequent fogs and little sunshine, continued for four weeks, the weekly number of deaths rising from 1700 to 1971, 2023, 2632, and 2188. The deaths from acute diseases of the lungs in these weeks were respectively 279, 481, 566, 881, and 689, showing that a large proportion of the excessive mortality was caused by these diseases. At the end of November and in December of the same year there was a rapid fall of temperature, when the number of deaths from acute diseases of the lungs rose from 297 to 358, 350, 387, 541, 553, and 389 in the respective weeks. From November 29 to December 9 the sun was seen only on two days for 4½ hours, and from December 9 to the 18th also on two other days for less than 4 hours, making the total amount of sunshine 8·1 hours only in 20 days. In January and February the excess of weekly mortality from all diseases reached the large number of 504 deaths; in December it was less, the fogs not having been so dense, but the excess equalled 246 deaths per week.

The relations between a high summer temperature and excessive mortality from diarrhœa have long been well known, but the immediate cause of the disease as an epidemic is not known. Summer diarrhœa prevails to a greater extent in certain localities, notably in Leicester (and has done so for years); and the cause has been carefully sought for, but has not been found out. Recent researches, however, point to a kind of bacillus as the immediate cause, as it has been found in the air of water-closets, in the traps under the pans, and in the discharges from infants and young children. In order to indicate more readily how intimately the mortality from diarrhœa depends on temperature, I now lay before you a table showing the mean temperature for ten weeks in summer, of seven cold and hot summers, the temperature of Thames water, and the death-rates of infants under one year per million population of London:—

London. Deaths under 1 Year, in July, August, and part of September, from Diarrhœa per 1,000,000 Population Living at all Ages, arranged in the Order of Mortality

	Mean temperature, 10 weeks	Temperature of Thames water	Age 0-1 year. Deaths from diarrhœa per 1,000,000 population living at all ages
1860	58·1	60·6	151
1862	59·0	62·0	189
1879	58·7	60·7	228
1877	61·2	63·3	347
1874	61·7	63·8	447
1878	63·7	64·1	576
1876	64·4	64·9	642

As may be seen, the deaths of infants under 1 year of age from diarrhœa per 1,000,000 population was only 151; whilst the mean summer temperature was only 58°·1 F. against 189 in 1862, when the mean temperature was 59°·0. In 1879, when the mean temperature was 58°·7, the deaths from diarrhœa rose to 228 per million, but a few days were unusually hot. In 1877 the mean temperature of the air was 61°·2, of the Thames water 63°·3, and the mortality of infants from diarrhœa 347 per million population. In 1874, when the mean temperature of the air was 61°·7, the mortality rose to 447 per million; and in the hot summers of 1878 and 1876, when the mean air temperatures were 64°·1 and 64°·9 respectively, the death-rates of infants were 576 and 642 per million population. The relations, therefore, between a high summer temperature and the mortality from diarrhœa in infants are very intimate. I have selected the mortality amongst infants in preference to that at all ages, as the deaths occur more quickly, and because young children suffer in greater proportion than other persons.

The proportionate number of deaths at *all ages* from diarrhœa corresponds pretty closely with those of infants. To prove this, I made calculations for three years, and ascertained that only 3·9 per cent. of all the deaths from this disease were registered in the weeks having a temperature of less than 50°; 11·9 per cent. in the weeks having a temperature between 50° and 60°, whilst in the comparatively few weeks in which the temperature exceeded 60° F., as many as 84·2 per cent. of the total number of deaths was registered. In the sixteen years, 1840-56, for which many years ago I made a special inquiry, only 18·9 per cent. of all the deaths from diarrhœa occurred in winter and spring, against 81·1 per cent. in summer and autumn. In the twenty years, 1860-79, there were seven years in which the summer temperature was in defect when the mortality per 100,000 inhabitants of London was 200; whilst in ten summers, during which the temperature was in excess by 2° or less, the mortality was 317 per 100,000. The mean temperature was largely in excess, that is to say, more than 2° plus in three of these summers, when the mortality reached 339 per 100,000 inhabitants. These figures show that great care should be taken in hot weather to prevent diarrhœa, especially amongst young children; by frequent washing with soap and water to ensure cleanliness, and proper action of the skin; by great attention to the food, especially of infants fed from the bottle; free ventilation of living rooms, and especially of bedrooms; and by protection, as far as possible, being afforded from a hot sun, as well as by avoiding excessive exercise. All animal and vegetable matter should be removed from the vicinity of dwelling-houses as quickly as possible (indeed these should be burnt instead of being put in the dust-bin), the drains should be frequently disinfected and well flushed out, especially when the mean daily temperature of the air is above 60° F.

Time will not admit of more than a mere mention of the relations between meteorological phenomena and the mortality from many other diseases and affections, such as apoplexy from heat, sunstroke, liver diseases, yellow fever, cholera, whooping-cough, measles, &c., especially as the state of our knowledge on the subject is so very limited. A comparison between the mortality from several diseases in this and other countries shows that certain of these do not prevail under closely corresponding conditions. Thus the curves of mortality from whooping-cough, typhoid fever, and scarlet fever, do not correspond with the curves of temperature in both London and New York, and the same may be said of diarrhœa in India. It is therefore evident that some other cause or causes than a varying temperature must be concerned in the production of an increased death-rate from these diseases. The subject is of great importance, and I do not despair of our obtaining some day a knowledge of the agents through which meteorological phenomena act in the production of increased and decreased death-rates from certain diseases, and the means by which, to a certain extent, these injurious effects on man be prevented.

Mr. R. H. Scott, F.R.S., read a paper on "The Equinoctial Gales—do they occur in the British Isles?" Most scientific meteorologists, Mr. Scott stated, are disposed to give up, almost in despair, the idea of eradicating from the popular mind the belief in the influence of the moon on the weather. There is, however, another belief, not quite so widely spread, but still very generally accepted, which attributes to the equinoxes a peculiarly stormy character. Over and over again have I heard the remark that it would be well for those proposing to take a voyage to wait until the equinoctial gales were over. It has struck me, therefore, that as we have had for several years past a regular system of storm warnings, it might be of interest to ascertain if the record of these warnings, and of the storms with which they were connected, exhibited any maximum of storm frequency about the equinoxes.

The period I have taken has been that of the fourteen years beginning with the spring of 1870, and I have commenced with the spring in order to include the past winter, that of 1883-4. With the year 1870, the systematic checking of storm warnings was commenced on the demand of the late Colonel Sykes. The results were published as "Parliamentary Papers" for the first seven years, and subsequently the returns have been regularly prepared in the Meteorological Office, though only the summary of results has appeared in the Annual Reports. As these returns give not only the storms for which warnings were issued,

but also those for which none were sent out, they afford a ready index to the storms which have been felt on the coasts.

Only such storms have been selected as have been really severe, such as have attained force 9 of the Beaufort scale at more than two stations, with a velocity exceeding 50 miles an hour recorded by an anemograph for more than a single hour. I have also not discriminated between the directions from which the strongest winds were felt.

The results of these records show that gales are of no greater frequency at the equinoxes than at any other time.

The diagrams show that the storms are all but exclusively confined to the winter half-year, if we take that to include part of the autumn and spring.

The diagrams show that there is no strongly-marked maximum at either equinox, but they do exhibit indications of periodicity which are very interesting.

Leaving the summer alone, as not worth notice, the frequency rises from nine and eight in the periods preceding the autumn equinox to ten at that epoch. The curve then rises rapidly, the value doubling itself and trebling itself in the two succeeding intervals. We then find a falling off at the time of the Martinmas summer in the first half of November, and a second maximum in the end of that month—the period indicated by Sir John Herschel long ago, in an article in *Good Words* for January 1864, as that succeeding what he called "The Great November Wave," a phenomenon which does not receive as much attention now as formerly. The first part of December is comparatively quiet, but after that the frequency rises to its absolute maximum at the latter half of January, from which period the curve descends gradually, with one decided check in February, to the same value which it had in August, and which it attains at the end of April. The check in February reminds us of the well-known tradition of the "halcyon" days at the end of winter. The frequency at the spring equinoctial period is nearly double what it is at the corresponding interval at the autumn equinox, being 19 as compared with 10. In one particular, however, the phenomena agree—the equinoxes are periods of sudden change in storm frequency. In the autumn this rises from 10 to 20 as soon as the equinox is passed; in the spring it falls from 27 to 19 as the equinox arrives. Accordingly, persons who wait till the equinox is passed in autumn improve their chances of falling in with a storm, for the diagram shows no signs of a lull once a heavy storm has occurred. In the spring it would apparently be wise to wait till April was well advanced, if you wished to get calm weather in the Bay of Biscay.

If we now look to see what evidence of recurrence of storms for particular short periods is discoverable in our data, we find that the day most frequently so distinguished is January 1, on which a storm was recorded six times in the fourteen years. This is very remarkable, as December 31 only shows one, and January 2 only two storms. Five days—November 10 and 20, January 18 and 19, and February 26—show five each, and no less than sixteen days show four. The stormiest two-day interval is that of January 18 and 19, which, as just explained, exhibits five storms each. The most disturbed three-day period is that of January 24 to 26, where we find four storms on each day. The date of the Battle of Trafalgar, October 21, is marked by two fours, on the 21st and 22nd, but the end of October is not so disturbed as the end of January.

The diagram also shows that almost every month in the year is occasionally nearly free from storms. October, November, December, and January have only one apiece, but in different years. March is the only month which has at least two storms, thus justifying its epithet, "March many-weathers."

Mr. Scott also read a paper on Cumulative Temperature, of which the following are the leading points:—

On the walls of the Meteorological Annexe will be found a series of diagrams, exhibiting from various districts in the United Kingdom, in a graphical form, the March of Temperature, Rainfall, and Bright Sunshine, from the beginning of the present year, and also for the entire year 1881, which is reproduced for purposes of comparison.

The object of these curves is to show clearly some of the most important factors in the growth of crops.

It is proved, almost beyond a doubt, that each plant, say each individual cereal, requires a definite amount of heat to bring it to maturity. Thus, maize requires more than wheat, and wheat again more than barley or oats.

Now various investigators, and notably Boussingault and Prof. Alphonse de Candolle, of Geneva, have devoted much attention to this subject, and the latter writer, in his "Géographie Botanique," has come to the conclusion that a certain total amount of temperature above a definite base line is necessary for plant growth, and that this amount, or, as he calls it, this "sum of temperature," varies for each crop.

He found that plants, as a rule, did not begin to give indications of active vegetation until the temperature rose above 6° C. This temperature, 6° C., or, in round numbers, 42° F., that is ten degrees above the freezing point, is taken as the base for all the diagrams. Although Prof. de Candolle propounded his views some years ago, as recently as the year 1874, at the Agricultural Conference at Vienna, meteorologists were quite at sea as to how these sums of temperature were to be calculated.

The credit of solving this problem belongs to Lieut.-General Richard Strachey, the Chairman of the Meteorological Council. In the first place he proposes to adopt a certain unit of temperature to supply a standard for calculation, the unit being one degree continued for the unit of time, either one hour or one day, as the case may be. Such a unit may be conveniently called an hour degree, or day degree. The unit of time adopted for the calculations to which I am about to refer is a day, and the unit of what may be termed the effective temperature is therefore *a day degree*. A day degree therefore signifies 1° F. of excess or defect of temperature above or below 42° F. continued for twenty-four hours, or any other number of degrees for an inversely proportional number of hours.

Now the first idea I want you to take in about these day degrees is that when we speak generally of the mean or average temperature for a day, or month, or year, we imply that the resulting temperature is the same as would be observed if the thermometer indicated this mean temperature throughout the entire period for which the mean is taken. Thus, if we were dealing with daily means, an average daily temperature of 62° F., which is an ordinary temperature for a warm summer's day, would mean twenty day degrees of temperature for that day, starting from the assumed base line of 42° F., which has already been mentioned.

The first step therefore towards determining this effective temperature in day degrees resolves itself into determining as speedily and simply as possible the average temperature for the period under consideration.

We have, fortunately, to our hands, a very simple mode of arriving at the mean temperature with accuracy sufficient for our purposes. Almost all observers record the maximum and minimum temperatures once in the twenty-four hours. It is found that the half sum of these readings, the mean between them, is nearly but not exactly the average for the day. It must, of course, be understood that the instruments must be read regularly and at the same hour every day.

The next points which require attention are: whether the maximum and minimum are both above 42°, which occurs in summer, or both below that point, which occurs in winter; or, finally, whether one is above, and the other below. In the first case all the accumulated temperature is to the good; it is all on the positive side. In the second case it is all on the negative side. The third case is the only one which presents difficulty, for when the extreme temperatures are on either side of the line of 42°, one portion of the effective temperature for the day is positive, and the other negative.

Now, General Strachey carried out a long series of calculations, based on the observed hourly temperatures at Kew Observatory, and at other stations in the United Kingdom, in order to ascertain the magnitude of the co-efficient by which the difference between either of these extreme temperatures and the base temperature (42° F.) should be multiplied in order to obtain the values of the temperatures in excess or defect of 42° F. expressed in day-degrees, and he found that this, *for a weekly period*, was 0·4.

Accordingly we get the following rules:—

If the mean of the day is above 42° F., we multiply the difference between the minimum and 42° F. by 0·4 (four-tenths), and call this *the negative effective temperature*.

To find the positive effective temperature we subtract from the difference between the mean for the day and 42°, the negative effective temperature just determined.

If the mean of the day is below 42° F. the proceeding is similar; but we first ascertain the positive effective temperature, and subtract that from the difference between 42° F. and the mean, thus obtaining the negative effective temperature.

The method of determining the effective temperature, which may briefly be called the accumulated temperature, is fully explained in a paper by General Strachey, which will appear in the forthcoming volume of the "Quarterly Weather Report," that for 1878. Meanwhile it is extremely interesting to examine the diagrams in the Annexe somewhat minutely, and to observe how the total accumulated temperature, say, up to July 1, is made up in very different ways in the two years, 1881 and 1884, there exhibited.

The year 1881 was very cold in the winter, and its accumulated temperature was made up in the spring and early summer. In the present year we had practically no frost, but then we had unusually cold weather at Easter and at the end of May.

The practical application of the data thus obtained as standards of comparison for the growth and ripening of various agricultural products must of course be left to the agriculturists, and it will be interesting to learn how far a correspondence between the character of the several crops and the accumulated temperature of the year can be established.

The measure of temperature afforded by this system of computation appears to be as well suited to supply a standard of comparison of climates for hygienic purposes as for agriculture, and the diagrams indicate in a forcible manner the characteristic differences of climate, in respect of temperature, of the portions our islands to which they refer.

Mr. William Marriott read a paper on "Some Occasional Winds and their Influence on Health." After referring briefly to the causes of winds, Mr. Marriott spoke of the East wind, the Mistral, the Sirocco, and other well-known occasional winds. Of the East wind, Mr. Marriott said it was the most dreaded in this country. It is usually dry, cold, and very penetrating, and is well described in the old saying—

"When the wind is in the East
'Tis neither good for man nor beast."

Dr. Arthur Mitchell, in a "Note on the Weather of 1867, and on some effects of East winds," says, "Such winds blowing over a moist surface, like that, for instance, of the human body, tend to reduce the temperature of that surface to the temperature of evaporation, which in this case is much below that of the air itself. In licking up the moisture — that is, in causing its evaporation — a large amount of heat is rendered latent. This heat must be taken from something, and, in point of fact, our bodies are, and must be, atmost its entire source. A cold and dry wind, therefore, cools the surface of our bodies, not simply by enveloping them in a cool medium, and warming itself by conduction at their expense. It does this of course; but, being dry as well as cold, it does it with less activity than it would if moist and cold—damp air being a better conductor than dry air. It is chiefly, however, by the other mode that dry cold winds abstract heat from our bodies,—that is, by using their heat in the conversion of moisture into vapour. The heat so used becomes latent, and is for the time being lost. It does not raise the temperature of the air in immediate contact with the body. On the contrary, that air itself, low as its temperature may be, gives up some of its heat to become latent in the vaporised moisture, and probably gives up more than it gains from our bodies by conduction, so that the temperature of the film of air actually in contact with our bodies may be, and probably is, a little lower than the temperature of the bulk. The quantity of heat which our bodies lose in this way is far from insignificant, and the loss cannot be sustained without involving extensive and important physiological actions, and without influencing the state of health. In feeble and delicate constitutions, the resources of nature prove insufficient to meet the demand made on them, and a condition of disease then ensues." —(*Journal* of the Scottish Meteorological Society, vol. ii. p. 80.)

SCIENTIFIC SERIALS

Proceedings of the Linnean Society of New South Wales, vol. viii. part iv. contains:—Occasional notes on plants indigenous in the neighbourhood of Sydney, by E. Haviland.—Temperature of the body of *Echidna hystrix*, by N. de Miklouho-Maclay.—Plagiostomata of the Pacific, part 2, by N. de Miklouho-Maclay and W. Macleay, F.L.S.—Notes on some reptiles of the Herbert River, by W. Macleay, F.L.S.—Notes on some customs of the aborigines of the Albert district, by C. S. Wilkinson, F.G.S., F.L.S.—On the brain of Grey's whale, by W. A. Haswell, M.A., B.Sc.—On a new genus of fish from Port Jackson, by W. Macleay, F.L.S.—Fishes from the South Sea Islands, by Charles De Vis, M.A.—Some results of trawl-fishing outside Port Jackson, by W. Macleay, F.L.S.—The "Barometro Araucano" from the Chiloe Islands, by N. de Miklouho-Maclay.—Far southern localities of New South Wales plants, by Baron Sir F. von Müller, K.C.M.G., F.R.S.—Description of Australian Micro-lepidoptera, part 10, by E. Meyrick, B.A.—Notes on the geology of the southern portion of the Clarence River basin, by Prof. Stephens, M.A.—Dimensions of some gigantic land-tortoises, by J. C. Cox, M.D., F.L.S.

THE *Zeitschrift für wissenschaftliche Zoologie*, vol. xl. part 1, contains:—P. M. Fischer, upon the structure of *Opisthotrema cochleare*, nov. genus et spec.: a contribution to the anatomy of the Trematoda.—F. Blochmann, remarks upon some Flagellates.—A. Korotneff, the budding of Anchinia.—L. Döderlein, studies of Japanese Lithistidæ.—J. Brock, the male of *Sepioloidea lineolata*, d'Orb. (*Sepiola lineolata*, Quoy and Gaim), with general remarks upon the family of Sepioladæ.—A. Gruber, upon the nucleus and nuclear-fission in the Protozoa.—O. E. Imhof, results of a study of the pelagic fauna of the Swiss fresh-water lakes and tarns.

Part 2 contains:—A. Kölliker, the embryonic germinal layers and tissues (with a postscript).—C. K. Hoffmann, contribution to the history of the development of reptiles.—P. Langerhans, the worm-fauna of Madeira.—F. Ahlborn, (1) upon the origin and exit of the cerebral nerves in Petromyzon; (2) upon the segmentation of the body in Vertebrates; (3) upon the importance of the pineal gland (conarium, epiphysis cerebri).—C. Emery, study of *Luciola italica*, L.

THE *Morphologisches Jahrbuch*, vol. ix. part 3, contains the following:—G. Ruge, contributions to the study of the hæmal system in man.—J. E. V. Boas, a contribution to the morphology of the nails, claws, and hoofs of the Mammalia.—M. Davidoff, on the variations of the plexus lumbosacralis of *Salamandra maculosa*.—O. Bütschli, remarks upon the gastræa theory.—C. Gegenbaur, on the accessory tongue (*Plica fimbriala*) of man and other mammals.

Vol. ix. part 4 contains:—M. Sagemehl, contributions to the comparative anatomy of fishes, ii., some remarks upon the membranes of the brain in bony fishes.—P. Lesshaft, upon the muscles and fasciæ of the female perineum.—H. Klaatsch, contributions to a more exact knowledge of the Campanularia.—G. Baur, the carpus of the Artiodactyles: a morphogenetic study.—G. Gegenbaur, contributions to the anatomy of the mammary organs in Echidna.

SOCIETIES AND ACADEMIES

EDINBURGH

Mathematical Society, July 11.—Dr. R. M. Ferguson in the chair.—Prof. Chrystal contributed three papers on the application of the multiplication of matrices to prove a theorem in spherical geometry, on the discrimination of conics enveloped by rays joining the corresponding points of two projective ranges, and on the partition of numbers; in connection with the second of these he indicated a solution he had received in a note from Signor Cremona of Rome.—Dr. Alexander Macfarlane gave illustrations of a common error in geological calculations; and Mr. A. Y. Fraser explained two solutions (by himself and Mr. R. E. Allardice) of a problem of arrangements entitled La Tour d'Hanoi, which appeared in the *Journal des Débats* for December 27, 1883.

PARIS

Academy of Sciences, July 28.—M. Rolland, President, in the chair.—On the rule of Newton as demonstrated by Sylvester; a sequel to the two previous communications, by M. de Jonquières. Here two cases of indeterminants are dealt with: (1) That in which several consecutive terms are wanting in the equation, the absence of one or more non-consecutive terms giving rise to no uncertainty; (2) that in which one or more of the quadratic functions intervening in the operation are identically nul.—A study of the deviations of the pendulum at Fort Loreto, Puebla, Mexico, two illustrations, by M. Bouquet de la Grye. These observations were conducted by means of a multiplying seismograph set up in connection with the expedition sent out to observe the transit of Venus. Their object was

to ascertain how far the oscillations of the ground and the phenomenon of tides may be determined by the vibrations of the pendulum in volcanic and mountainous regions.—Report of the Commissioners, MM. Gosselin, Pasteur, Marey, Bert, and others on various recent communications received in connection with the present outbreak of cholera in the South of France. The Commission has examined altogether 240 communications, mostly from Spain, and either suggesting "infallible nostrums," or such remedies as are already in practice. Others recommend hypodermic injections of the nitrate of pilocarpine, arsenic, copper, phenic acid, salicylic acid, vapour of hyponitric acid, intra-venous injections of pure water, or mixed with chloride of calcium or other salts. All these methods have been tried, mostly with indifferent results, although phenic acid and the intra-venous injections seem to call for further consideration. But, speaking generally, the Commission regrets to have to report that none of the communications contain any really useful suggestions.—On a new application of electricity to the treatment of fibrous tumours of the womb, by M. G. Apontoli.—Researches on wheaten and other flours; distribution of the acid and saccharine elements in the various products of the corn-mill, by M. Balland.—Note on the analytical calculating machine invented by Charles Babbage, by General F. L. Menabrea. The author gives a full description of the machine left incompleted by the inventor. He also gives an unpublished letter of Mr. Babbage, dated August 28, 1843, and certifying that the anonymous English translation of Signor Menabrea's original account of the machine, which appeared with some brilliant accompanying explanations in the third volume of the *Scientific Memoirs*, was by Lady Ada Lovelace, only daughter of Lord Byron.—Note on the exact number of the variations gained or lost in the multiplication of the polynome $f(x)$ by the binome $x^n \pm a$, by M. D. André.—Note on the temperature and critical pressure of the atmosphere. Relation between atmospheric temperature and the pressure of evaporation, by M. K. Olzewski.—Description of a new method of directly measuring absolute magnetic intensities, by M. A. Leduc. This method, which is an application of M. Lippmann's discovery, is extremely simple and expeditious. It enables magnetic intensities to be measured in absolute unities, and is now being applied by the author to the study of a magnetic field.—Note on the combustion of explosive gases in various states of dilution, by M. A. Witz.—Note on the quantitative analysis of nitric acid by precipitation in the state of nitrate of cinchonamine. Application of this process to the quantitative analysis of the nitrates contained in natural waters and in plants, by M. Arnaud.—Note on the triacetic ether of a butylic glycerine, by M. L. Prunier.—Note on a new method of making a quantitative analysis of the dry extract of wines, by M. E. H. Amagat.—Anatomical and physiological description of *Convoluta Schultzii*, a curious animal of relatively high organisation, but in which the association with chlorophyll elements has produced some interesting physiological phenomena, by M. A. Barthélemy. Although deprived of eyes even in the rudimentary state, these worms appear to possess a sort of visual sensation. The act of breathing by absorption of carbonic acid through the cuticle also presents a striking analogy to that of submerged aquatic plants.—Fourth contribution to the history of the formation of coal, isolated carboniferous blocks, from Commentry, by M. B. Renault.—Note on the microscopic organism associated with the zooglæic tuberculosis, by MM. L. Malassez and W. Vignal.—Note on a hitherto unobserved portion of the sting of melliferous insects, and on the mechanism employed by them in expelling the venom, by M. G. Carlet.—Memoir on the geology of the Kepp district, Tunisia, one illustration, by M. P. Marès. The author determines in this district a regular superposition of the Upper Cretaceous, Eocene, and Miocene formations, a detailed study of which promises to be of great interest.—Note on the relations existing between the crystalline systems of various substances, by M. F. Mallard.

BERLIN

Physical Society, June 27.—Dr. König described a subjective optical perception of which he had repeatedly become conscious in the morning on waking from sleep and while his eyes were yet shut. On a blue-gray background he saw regular closely adjoining hexagons, like the cells of a beehive, the contours of which appeared black, while the upper sides and the outwardly adjoining sides of the hexagons had a yellow appearance interiorly, an effect produced perhaps by way of contrast to the bluish background. In the interior of each hexagon, but not exactly in the centre, and just as little uniformly in the different fields, a black point was visible. The radius of each figure was about the length of the diameter of the moon's image. In endeavouring to explain this phenomenon Dr. König thought first of the epithelial cells of the eye, which formed a similar mosaic behind the retina, and calculated the visual angle under which such a phenomenon was produced. From this calculation it appeared that these hexagons were considerably less than the subjective ones, as many as twelve epithelial cells being needed to tally with the field of the subjective figure. No other explanation of the phenomenon had yet been come upon by Dr. König.—Prof. Neesen gave a short survey of the methods that had hitherto been proposed with a view to regulating the electric current in its technical application. No method, it appeared, had yet been introduced into practice, and for the present the question turned only about proposals on points of principle. These were divisible into such as sought to regulate the energy by changing the resistance, and into such, on the other hand, as attempted this object by changing the electromotive force. The change in resistance was effected at first by means of the hand, and later in different ways automatically. The change of electromotive force in the case of dynamic machines was sought in part by regulation of the propelling steam-engine, in part by change of the magnet, in part by means of a second counteracting engine, in part by changing longitudinally the wire pulleys, and in part by opposed windings of the rolling wires. Thirdly, and lastly, it was proposed as a means towards regulating the electric current, that when the dynamic machine delivered more electricity than was used, the surplus should be diverted to the supply of an accumulator where, when the machine yielded too feeble a current, the supplementary energy required could be drawn. Prof. Neesen gave a more detailed account of some of these proposals, and concluded in favour of the last or third method, that, namely, of the transference and storage of surplus energy in an accumulator, as the most advisable of all the plans proposed from a practical point of view.

THE REPORT ON TECHNICAL INSTRUCTION

THE Report of the Royal Commissioners on Technical Instruction is now before the public. These two volumes, together with the short interim Report on Apprenticeship Schools in France, which was issued two years ago, extend over a wide range of matter. The Commissioners' account of their travels abroad and at home is narrated in vol. i., which concludes with their various recommendations. Vol. ii. contains a Report on Agricultural Education, by Mr. Jenkins, and another on Technical Education in America, by Mr. Wm. Mather. In the remaining volumes will be found a Report by Mr. Wardle on Silk Industries, and a scheme by Prof. Sullivan for Technical Education in Ireland, and a variety of Statistics and Programmes are also promised.

The immense mass of detail thus gathered together in this voluminous and interesting blue-book renders it a matter of some difficulty to give anything like an adequate review of the labours of the Commission. In the present article we shall confine our attention to that part of the Report which deals with technical schools in foreign countries, reserving for a second notice that part of the Report which relates to Great Britain.

The Commissioners preface their account of Continental Technical Instruction with some concise introductory notices of the general conditions of Primary and Secondary Education in various nations. Their remarks on the gradation of schools, on the use of school museums, and on the prominence given to drawing are worthy of attention. After these notices the Commissioners deal with artisans' evening technical schools, artisans' apprenticeship schools, intermediate technical schools for foremen, trade and professional schools for women, and the higher technical instruction for employers and managers. Concerning the first of these matters the Commissioners remark on the value of the numerous continuation-schools (Fortbildungschulen) which exist in nearly all towns of Germany and Switzerland. It appears that in Bavaria, Baden, and elsewhere, pupils leaving the primary schools at the age of 13 are compelled by law to continue their studies in the evening schools until the age of 16: a truly wise rule, calculated to sustain the benefits of school training at a period when such training is too often prematurely cut short. It also appears that although in no country abroad is there any organisation for systematic evening instruction at all comparable to that under the control of our Science and Art Department, the teaching, at least in many foreign towns, is conducted by professors of higher standing than, and of superior attainments to, the ordinary English "science-teacher" who, it must be confessed, is too often sadly deficient in training. On the subject of artisan apprenticeship schools the Commissioners do not add much to the information given two years ago in their preliminary report, so far as France is concerned; but, in relation to some of the German schools, as, for example, the clock-making and wood-carving schools at Furtwangen and other districts of the Black Forest, there is much interesting information. In Wurtemburg there are no such schools, as the authorities prefer to attempt to give sound education by means of evening and Sunday schools, without interfering with the conditions of daily labour.

In regard to Intermediate Technical Schools for foremen and others much is being done abroad, both in the special departments of weaving, mining, and industrial art, and in more general schools. In France particularly this is the case. The great schools of this type at Lyons, Rheims, and Paris are practically unique. There is nothing approaching them in this country except perhaps the Allan Glen's Institution in Glasgow. These schools and the secondary technical schools of Germany are elaborately described. The Higher Trade Institute of Chemnitz, and the four "Industrie Schulen" of Munich, Augsburg, Nüremberg, and Kaiserslautern are of this class, intermediate between the Real-Schulen and the Polytechnics. No classics are taught in these schools. Throughout Austria, Germany, France, and Holland there are also special schools for mining and for the building trades. The Commissioners devote many pages to the weaving schools, which, like those of Chemnitz, Crefeld, and Mulhouse, are to be found doing work of utmost importance to the continental industries. The spirit with which municipalities and manufacturers support these schools is truly remarkable. Employers are constantly looking out for students who have attended the technical classes. The manufacturers feel it imperative to extend their work in order that in troublous times they may have more than one string to their bow. Thus in Crefeld, where silk goods are the staple manufacture, much attention is given in the weaving school to the weaving of jute, wool, and cotton. The people cheerfully tax themselves to pay for efficient management. They recognise that the day has gone by when money can be made without effort: "to exist they must move on." Heavily taxed as the German people are by the burden of enormous civil and military expenditure, they yet believe that it is cheapest in the long run to educate the "human machine" to the highest pitch of perfection.

It is, however, with the higher technical instruction, with the great Polytechnic colleges of Germany, and with the École Centrale and École Polytechnique of Paris that the interest of the Commissioners' Report culminates. The German Polytechnics form a group of institutions of which the type is absolutely wanting in this country. These institutions, though in many respects resembling the German universities, differ absolutely from them, not merely in being technical and practical, but in having fixed curricula of study, and regular systems of examination. The eleven schools of this type (eight of which are in Germany proper, one at Zürich, one at Delft, one at Moscow) have been built at a cost of not less than three millions sterling, and are maintained at an annual cost of over 200,000*l.* This amounts to a State expenditure of about 100*l.* per annum for each student in attendance. This may be contrasted with the case of the two leading English Universities of Cambridge and Oxford. These and their colleges are believed to have a total annual income from endowments of 500,000*l.*, and as there are about 5000 men in total attending the two Universities, this also is at the rate of 100*l.* per annum per student. There is, however, room in the Polytechnic for three times the number of students

actually in attendance. A few figures respecting some of these schools will show how these institutions stand in public opinion. The Munich Technical High School cost 157,000*l.*, the apparatus alone being worth 36,000*l.*, and the annual expenses amounting to 20,000*l.* The Zürich Polytechnic spends 20,000*l.* annually, 13,800*l.* being derived from Federal taxes, and 3794*l.* only from fees. There are forty-five professors on the lecturing staff. 50,000*l.* have just been spent on laboratory extension. The Stuttgart Polytechnic has a State subvention of 12,000*l.*, that of Dresden 12,200*l.* The Hanover Polytechnic cost 350,000*l.*; its collection of models (chiefly engineering), 36,000*l.*, and 1250*l.* is spent every year in adding to the collection. Some idea of the preparation made for teaching engineering students may be gathered from the fact that there are stated to be in this one school no fewer than 673 tables for drawing. The Berlin Polytechnic, now nearly completed, has cost 450,000*l.*; that of Moscow 496,000*l.* The chemical laboratory of the Polytechnic of Aachen alone cost 45,000*l.* The Bernouillianum of Berne cost that little town more than 1*l.* per inhabitant! At such a price do our neighbours provide for the higher technical training. In France, too, the technical schools are maintained at great cost. In the École Polytechnique, salaries alone amount to 22,000*l.* per annum. A new addition to the laboratories is costing 96,000*l.* All this is found by the Government. On the other hand the École Centrale, which spends 17,836*l.* per annum, is self-supporting, the fees being very high..

From this enormous expenditure of money on Higher Technical Education, tangible results cannot but accrue. Many such are mentioned in the pages of the Commissioners' Report. They adduce examples of improvements in machinery which are the result to a large extent of students' training. They point out how in Continental chemical works and dye works there is a thoroughly trained chemist at the head of each separate department. They indorse the opinion of Prof. von Helmholtz as to the absolute economy of employing as heads of departments persons conversant with the theory of their work, and able by virtue of their scientific knowledge to anticipate results and to make quantitative calculations. They remark that in physics, as also in chemistry, the knowledge of the principles of the science and of the methods of research is the more important part of the equipment of the technical student. They ascribe the general diffusion of high scientific knowledge in Germany to the multiplication of the Polytechnics, and to the small cost of a higher or University education. Amongst the opinions, which they quote, of authoritative speakers, there is one of particular appositeness from the mouth of Prof. Quincke. He holds that it is an error to suppose that any Polytechnic course of instruction can *by itself* teach a student to erect an engine, work a blast-furnace, or manufacture sulphuric acid: he holds that lectures and laboratory work are obviously insufficient to prepare the student for carrying on work where actual practical experience is needed; but that, in contradistinction, the object of the Polytechnic School is *to facilitate the transition from pure science to practice.* The functions of the Polytechnic have probably never before been so well defined. It may be an open question what kind of training is the best to qualify a man to be manager of an industrial concern. But there can be no question whatever of the consensus of opinion on the Continent as to the value of the Polytechnic training. It may not, nay, cannot, supplant the experience of the workshop: but it gives something that no amount of mere workshop experience can give—something which, were it suitably introduced into industrial Britain, would supply the greatest industrial want of our time.

BRITISH MINING

British Mining, a Treatise on the History, Discovery, Practical Development, and Future Prospects of Metalliferous Mines in the United Kingdom. By Robert Hunt, F.R.S. 4to. Pp. xx. 944, 231 Woodcuts and 2 Folding Plates. (London: Crosby Lockwood and Co., 1884.)

THE title shows that the author's object is to describe the past and present condition of British metal mines, and to venture some prophecies as to their future. It requires a bold heart to attempt a work of this kind; but, as explained in the preface, Mr. Hunt's long connection with mines and his official position as Keeper of Mining Records have given him excellent opportunities for gathering information.

The work is divided into four books. Book I. gives a long historical sketch of British metal mining from the time of the Phœnicians downwards. With reference to St. Michael's Mount being their trading station, the author indorses the old Cornish tradition and disagrees (p. 845) with Prof. Rhys, who has suggested that the Isle of Thanet was the *Iktis* of Diodorus. From detached memoirs and reports much information has been collated concerning mining work carried on by the Romans for lead, iron, copper, and gold.

In Chapter III., upon mining to the eighteenth century, Mr. Hunt fixes very exactly the date of the introduction of gunpowder for blasting in Cornish mines. Chapters IV., V., and VI., relating to the mining of tin, copper, lead, silver, iron, and zinc to the end of the eighteenth century, are full of valuable facts, and both here and in Chapter III. we notice many interesting statements concerning the special privileges of miners and the charters granted to them.

Book II., occupying one-third of the volume, is devoted to the formation of metalliferous deposits. The rocks and mineral veins of the principal mining districts are described, and long quotations are made from sundry writers. Mr. Hunt then sets forth the hypotheses of the best-known authors concerning the origin of lodes, and very wisely does not bind himself to any particular theory; he admits that mineral veins have been formed by deposition in fissures from lateral infiltration, from surface-water carrying down soluble salts they have dissolved out in their passage, and lastly, from ascending mineral springs. He further considers that many of the conditions observed are due to electro-chemical influences.

In the last chapter of this book the author brings forward instances of remarkable tin, lead, and copper mines in Cornwall, Wales, Ireland, and the North of England.

Book III., which is of the same length as the preceding one, is a treatise on practical mining. Rock-boring by machinery very properly comes in for a large share of attention, but some other departments of mining are

treated rather cursorily. In speaking of the *man-engine* for raising and lowering men, Mr. Hunt points out that the reason why this valuable invention is so little used is "the unfortunate system under which the mines of Cornwall and Devon are worked—a system which does not encourage the holder of shares to take any interest in the mines themselves, his interest being confined to the market value of the shares which he holds." This remark is unhappily applicable to other districts.

In Chapter IV., on ore-dressing, after an historical sketch, the principles of the mechanical preparation of ores for the smelter and the various kinds of machines now in use are described with the aid of numerous illustrations.

Chapter V., upon the discovery and extraction of iron ores from veins and other deposits, is disappointing, on account of its meagreness compared with the space devoted to less important metals, and the Cleveland ore should scarcely have been dismissed in a dozen lines.

Book IV. relates to the future prospects of British mining. To persons interested in mines, whether as owners, shareholders, workmen, or merchants furnishing them with supplies, this book will no doubt seem the most important in the volume. Mr. Hunt is not sanguine about better prices for tin, and he says that "it is improbable that our native copper mines can be expected to prove profitable for some time to come"; in the case of lead he evidently is not more hopeful, and though the prospects as regards zinc are brighter, still we are unable to supply our own wants. In spite of the productiveness of our iron mines, we have to import more than three million tons of iron ore annually.

The fourth chapter of this book contains numerous useful suggestions for working mines, and is well worthy of consideration by miners and shareholders in mines. With reference to profitable mining, Mr. Hunt says (p. 868):—"The question is frequently asked, Is British mining a remunerative pursuit? Various replies might doubtless be given in accordance with any particular set of views and opinions held on the subject, but mines promoted by mere speculation can scarcely be expected to become profitable, inasmuch as they are too frequently grounded upon a misrepresentation of facts, while the capital connected with them is often largely diverted to the pockets of individuals whose main purpose is immediate gain. Further, the management or conduct of affairs is often leavened with ignorance and incompetency; the acquisition of personal gain, at the cost of unsuspecting shareholders, being unfortunately sometimes the rule of action." No one who knows anything about mining can fail to indorse these remarks.

In Chapter V., which contains the general summary and conclusion, Mr. Hunt says that "the exhaustion of our mineral wealth is now going onward at a rapidly increasing rate," and the question arises whether we can meet the demands of trade from British mines or not. According to the author, our tin ore is practically inexhaustible, but for copper, lead, zinc, and silver we must depend greatly upon foreign and colonial mines; of iron ore we have enough for some years, though certain foreign ores are of importance to us.

The situation is summed up as follows:—"Without great improvements in the principles of mining it will not be possible to work, at a profit, many of our deeper and more extensive mines."

The last two pages of the work, before the appendix, contain several important maxims which deserve the careful study of all persons engaged in mines, such as the necessity of supplying pure air *at any cost*, of raising and lowering the men by machinery, and providing for them in the event of accident or disease. The concluding words very properly strike at the rascality which has done much to wreck British metal mining. "Beyond these, to enable the adventurers in our Home Mines to compete satisfactorily in the metal markets with the proprietors of colonial and foreign mines, and to realise a profit on the sale of their minerals, it is absolutely necessary to study the strictest economy, and to establish—beyond the risk of any failure—the highest principles of honesty in every department, directly or indirectly, connected with British Mining."

The size of Mr. Hunt's volume is apt to alarm the reader, and the publishers would probably have done better by issuing the work in separate books. It strikes us, too, that undue prominence is given to tin, to the detriment of the more important metal iron. From the "Mineral Statistics" for 1883, we see that the iron ore raised had a value of about 5¼ millions sterling, whereas the value of all the other metalliferous ores put together was only 1½ million. However, in spite of this favour shown to tin and of occasional inaccuracies, Mr. Hunt's *magnum opus* is very praiseworthy, as it contains a vast store of useful information, and the antiquary, the miner, and the capitalist are greatly indebted to him for having taken the trouble to chronicle so many valuable facts relating to such an important branch of British industry as Metal Mining.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The International Geological Congress

WILL you allow me to announce in your columns that, in consequence of the outbreak of cholera in the South of Europe, the International Geological Congress is postponed to September 1885.

JOHN MCKENNY HUGHES

Woodwardian Museum, Cambridge, August 12

The Volcanic Dust Phenomena

I WOULD draw the attention of such of your readers as may be travelling in Switzerland or other mountainous countries to the circumstance that in the clear atmosphere of the mountains the great corona or circle round the sun, as well as the semicircle seen opposite the sun before and after sunset continue to be markedly conspicuous; and the higher one ascends the more striking these phenomena are. I saw both the phenomena especially remarkable on the Gornergrat, altitude 10,289 feet, on the 21st and 22nd of last month; and even as low as 4000 feet they are decidedly more striking than at sea-level. It appears, therefore, that the bulk of the volcanic dust, if such it be, that still remains continues at a great elevation, and the prediction made last autumn that it might remain for years in the atmosphere, seems likely to be fulfilled.

The explanation of the strange sunsets given by "F. A. R. R." in NATURE (p. 155), seems a good one, except as regards the green appearance of the moon and stars; I must confess I am

not convinced that this was anything but a subjective phenomenon. It is true I saw it myself when there was little if any redness perceptible in the sky; but the probability is that one's eyes had become so dazzled by, and used to, the intense redness previously existing, that one was rendered incapable of seeing a moderate degree of red, and the complementary colour was produced in uncoloured objects. Besides, gas-lights sometimes partook of this colour. As regards the sun, I agree with "F. A. R. R." in the impression that when it was moderately near the horizon it was whiter than usual all last winter and spring, and perhaps to the present time.

Sunderland, August 6 T. W. BACKHOUSE

Upon the Occurrence of Bacteria and Minute Algæ on the Surface of Paper Money

THE recent researches of Paul Reinsch of Erlangen have shown the occurrence of different schizomycetes and of two new minute algæ (*Chroococcus monetarum*, *Pleurococcus monetarum*, Paul Reinsch) on the surfaces of the coins of many nations, living in the thin incrustations of organic detritus (composed especially of starch grains, fibres, &c.) deposited upon their surfaces in the course of long circulation. This extremely thin incrustation renders the coins very suitable for this micro-vegetation, but the same phenomenon is also exhibited in the case of paper money, and indeed by notes of clean and, to the unassisted vision of a quite unaltered appearance.

Having scraped off some of these minute incrustations with a scalpel and needle and divided them into fragments in recently boiled distilled water, with lenses of high powers (1/10th inch of Messrs. Beck) there were distinctly seen various schizomycetes, &c.

I have investigated the Hungarian recent and older (from the year 1848-49) bank and State notes, also Russian 1-rouble notes, and have found upon all of them—even upon the cleanest—schizomycetes, &c.

On the surface of all the paper money is always to be found the bacterium of putrefaction (*Bacterium termo*, Dujardin).

In the thin incrustations of paper-money the occurrence of starch grains, especially that of wheat-starch, linen, and cotton fibres, animal hairs, &c., are easily to be demonstrated, and upon the 1-forint [1] State-notes in such deposits the common saccharomyces are also to be found. Various micrococci, leptotriches (many with club-shaped swelled-up ends), and bacilli are also very frequent plants in these deposits on paper-money.

The two new species of algæ described by Paul Reinsch are very rare on the paper-money. The green pleurococcus cells I have observed in some cases on 1- and 5-forint State-notes and the bluish-green minute chroococcus on the edges of the 5-forint State notes.

The vegetation of the paper-money is, as a result of my researches, composed of the following minute plants:—

1. *Micrococcus* (various forms).
2. *Bacterium termo*.
3. *Bacillus* (various forms).
4. *Leptothrix* (various forms).
5. *Saccharomyces cerevisiæ*.
6. *Chroococcus monetarum*.
7. *Pleurococcus monetarum*.

From a hygienic point of view, also, the investigations of the commonest necessary household objects may not be superfluous, and I would especially call attention to these forms as occurring on the means of instruction, viz. the handbooks, &c., used by our young scholars.

JULES SCHAARSCHMIDT,
Privat docent of Cryptogamic Botany and Anatomy of Plants, Assistant at the Botanic Institute and Gardens, Royal Hungarian University, Kolosvár

[1] 1-forint (to German Gulden) = 2s.

Fireballs

THE following account I have received from a lady at Brühl near Cologne, July 26:—"8.22. A large fireball of scarlet fire almost as large as a harvest moon just sailed along and upwards, at a varying but mostly very rapid rate, until, at a great height, it remained for some minutes almost or quite stationary; then after some uncertain movements rose again, and rising, became smaller, until it finally disappeared. . . . Every one who saw it seemed petrified with amazement." This is of interest from the long time that the ball was visible, and its being seen by several people. I described some time ago some fireballs which I saw slowly moving at a distance during a storm in Egypt, which were then put down as illusory results of a flash (NATURE, vol. xxiv. p. 284), but now many similar cases have been lately reported. A large fireball, described as about a foot in diameter, was seen a few years ago near here; it struck a pavement, went over a low wall, moved across a wide lawn, and finally vanished in a wet ditch.

While living lately at San (Tanis), thirty-two miles south-west of Port Said, there occurred a most remarkable thunderstorm on May 12, lasting from 1.15 till 4 p.m. The rainfall in two hours was over 1½ inches; the hailstones (which covered half the area of the ground) were mostly 3/10ths to 4/10ths inch in diameter, and some 7/10ths, of concentric structure with jagged edges. Whenever I could hear anything above the battering of the hail on my iron roof there was always thunder going on; and as soon as the rain ceased I went out of doors, where for half an hour longer I can positively assert that there was not an instant of silence. This thunder was not in loud, reverberating peals, but was a continuous rushing, gusty, swishing sound; the noise rising and falling just like a gusty, tearing, high wind, without any crashes or explosive bursts, and with very little bumping or knocking sounds. It only lightened once or twice during that half hour, and there was but a faint breeze of wind. To the best of my belief the thunder was similar during the whole time of the storm, though with more explosive sounds and more lightning in the early part. It is impossible to refer such a storm to the ordinary instantaneous, sharp discharges with echoes, as the sound had no character of a reverberation; it appears to be due to a continuous discharge like that from a point. The storm was quite local, only extending a few miles. Since returning to England I have also heard thunder which was apparently not from an instantaneous discharge, as it began lightly and waxed louder for two or three seconds, until a loud crash of the main discharge took place.

The whole question of slow or peculiar discharges and of fireballs needs clearing up by careful observation; it is useless to ignore it or refer it to illusion, merely because we have not imitated it artificially or made a theory on the subject.

Bromley, Kent W. M. FLINDERS PETRIE

Museums

IN an excellent article on "Practical Taxidermy" in NATURE of August 7, reference is made to the Museum at Leicester as approaching to the ideal of what museums should be. While fully agreeing with the opinions attributed in that article to Mr. Bowdler Sharpe, and admitting that the Leicester Museum has at last taken one step towards the ideal which was worked out for it some years ago, I feel bound to point out to such other museums as are waking up to the necessity of a radical revolution, that perfection is a long way off yet; that there is ample room for each to do better than its predecessor; that Leicester has not even carried out the general principles laid down by Mr. Bowdler Sharpe; and that these general principles may be developed in various directions.

They should consider what a provincial museum can do to the best advantage, for the world, for local students, and for the unlearned public; and by what methods of arrangement, of public exhibition and of private access, its highest functions can be most completely brought out.

Of the three educational objects for which rates can be levied by Town Councils, viz. museums, free libraries, and art galleries, the popular taste is rather tending just now towards the free libraries and the art galleries. There is a disposition to regard museums as mere hobbies for the few, and to devote the lion's share of the rate to literature and art. This is perhaps only a swing of the pendulum, but it is justified to a large extent by the condition of nearly every provincial museum at the present time.

Science is taught in most museums as reading, writing, and arithmetic were taught in the old-dame schools—in a clumsy, thoughtless, perfunctory manner, which wasted half the time and interested nobody. Mr. Mundella, with the Education Act in his hands, has made a revolution in the schools; if Mr. Bowdler Sharpe will get his ideas developed in museums with equal success, he will supplement the schools in a most valuable and important direction.

His first principle, that the primary object of every county museum should be to make as perfect a collection as possible of the natural productions of that county, exhibited in the most attractive form, is undoubtedly correct, and has been definitely sanctioned by a large body of competent authorities. This is just what can be done by each provincial museum better than by any other institution in the world, and it is just what is especially wanted by scientists, by students, and by the public. But this unfortunately has not been made the primary object either at Leicester, Nottingham, or Derby.

Mr. Sharpe's second principle, that each museum should possess also a typical series of foreign specimens for comparison with the local ones is equally correct. Science depends upon the appreciation of similarities and differences. The faculty of careful observation and comparison is of such fundamental value in all education and might be so effectively cultivated in museums that these institutions will in the future be found essential adjuncts to the schools. But here all existing museums are particularly weak. Opportunities for comparison are not sought out. The collections are not arranged with any special view to making comparisons easy and obvious. If, for instance, the local birds are in one room, and the foreign types in another, comparison is made as difficult as possible. Even if they are on opposite sides of one gallery, and the divisions of the orders made exactly to correspond, it is still difficult. They must be brought so near together that the eye can match them as it would match two patterns. This can be accomplished, and in an artistic and very interesting manner. It is to be hoped that the museum of the future will work out Mr. Bowdler Sharpe's principles much more completely than has yet been done.

Birstal Hill, Leicester F. T. MOTT

Measuring Heat

DURING the past twelve months I have been endeavouring to construct some form of calorimeter which should aid me in the identification of minerals, and which should, to that end, combine accuracy with ease of manipulation. The avoidance of thermometry seemed highly desirable, and a *differential* method suggested itself.

One gramme of the mineral undergoing investigation, and one gramme of pure silver, are heated in the same steam chamber and simultaneously transferred into the muffles of two Favre and Silbermann's calorimeters, made of uniform size and placed side by side, similarly shielded from external sources of error during experiment. The specific heats are compared by the index movements of the calorimeters, the index tubes being either simply calibrated or empirically graduated.

Both calorimeters are here exposed to the same external sources of error. The amount of heat lost by radiation, however, will, for each calorimeter, depend on the duration of the experiment and the rise of temperature experienced. Now the heat received is communicated to the walls of the calorimeters by convection currents, ascending from the muffles, in the first instance, very much more slowly by conduction. It appeared, then, that an *internal* non-conducting shield of a porous nature lining the walls and retarding convection currents might reduce such loss very considerably. Experiment confirmed this supposition. An apparatus I have had constructed on this principle by Yeates of Dublin is now nearly ready for experiment.

Circular Rainbow seen from Hill-top

THIS is not such an unusual phenomenon. It depends of course on the position of the observer as regards the sun, and his "coin of vantage," viz. having a space below him. I have seen it several times in my life, and remember a beautiful illustration of it given by Mr. Bains, the artist who accompanied the traveller Chapman to the Victoria Falls on the Zambese. His painting was, and probably is, in the Library at Cape Town. He is represented as standing on a projecting rock overlooking the Falls, or perhaps I should say looking up the crevice into which the water falls, and in the centre of a glorious double circular rainbow. I have heard the picture much criticised and its accuracy doubted, but having had actual experience of such a sight, I always maintained its correctness.

I saw lately another "bow," which struck me as very remarkable—perhaps because I never saw one like it before. My house stands on a hill-top; below me at some distance is a piece of low ground, covered by the tide at high water. The sun was low behind me, and the "bow" was formed on a mist coming up from the sea and swamp. It was, however, so *flat* that it at once arrested my attention, and I called the members of my family to see a "flat rainbow"! All agreed they had never seen one like it. It was quite near us, as was proved by its intervening between certain objects; but I subsequently detected one part a long way to the left of me, showing it was, of course, a true "bow," but of an enormous size.

British Consulate, Noumea, June 17 E. L. LAYARD

THE MIGRATION OF SALMON

DURING the last ten years some exceedingly interesting researches have been effected by German, Finnish, Swedish, and Norwegian ichthyologists as to the migration of salmon on their respective coasts. Thus, by careful researches, some Swedish and Finnish *savants* have proved that the salmon, which in the summer are caught in the rivers of the upper gulf of the Baltic, have at another season, most probably in the winter, paid a visit to the shores and rivers of Northern Germany. This has been conclusively proved by salmon caught in the Swedish and Finnish rivers having German-made hooks in their gills and stomach. From this it is therefore apparent that, in the Baltic, salmon are in the habit of quitting the rivers of Northern Sweden and Finland in the autumn in order to visit the shores of Northern Germany during the winter, and return to their haunts in the spring. That the fish should be capable of performing the enormous journey across the Baltic—from the upper gulf to the Pomeranian coast—and back every year may indeed seem incredible, but that it is impossible is fully disproved by the experiments with salmon and trout effected by the late Mr. Frank Buckland on the coasts of Scotland and England in the same direction.

In March 1872 Profs. Virchow and Hansen were commissioned by the German Fishery Association to "mark" some of the salmon which had been hatched artificially near Hameln, in order to ascertain whether they were in the habit of returning to the river. The fish then in the hatching reservoirs were one year old, and mostly seven centimetres in length, although some were twice the size. Having tried cutting off various parts of the fins, it was found that it was most suitable for the object in view and the health of the fish to cut the so-called "fat" fin right away, particularly as the fish would retain this mark even when full grown.

On March 23 and 24, 1872, a thousand salmon marked in this manner were let out into the Weser. The marking was effected by taking the fish in the left hand, and then cutting the fin away with a pair of scissors, whereby the fish were perfectly uninjured. The little fat fin, which is mostly found on Salmonidæ only, contains no nerves of any importance, and has no particular function, so that its removal does not impair the fish in the least.

Ever since that year the fishermen between Bremen and Hameln have been on the look out for the marked fish, but not until a month ago a fish was caught, weighing 30 lbs., at Osterdeich, just above Bremen. The fat fin, which, on the fish one metre long, ought to have been six centimetres, was entirely absent; and, when the well-healed cut was felt, the hard membrane indicated that an operation had at one time or another been performed at this spot. The fish, which was marked as a grilse in 1872, was then thirteen years old—an age which in every respect corresponds with the age fixed by the fishermen. According to general observation, it has been demonstrated that the salmon in the Weser is, when one year old, from five to twelve centimetres long. In the second year it has been proved that the salmon go into the sea, and when they re-enter the river at four years of

age they weigh from eight to twelve pounds, and in the fifth year from twelve to fifteen pounds. From that age upwards the weight increases rapidly.

The results of the artificial hatching in the Weser are exceedingly promising. Thus the salmon fisheries at Hameln have been doubled in consequence during the last ten years, the tax at present paid to this town alone by the salmon fisheries being more than a thousand pounds.

In Norway, too, efforts have been made in the same direction during the last few years. Thus in 1883 the Storthing granted a sum of money for this purpose, and with this amount the Chief Inspector of Fisheries, Herr A. Landmark, has effected the marking of several hundreds of salmon and trout, chiefly on the west coast of Norway, during last autumn and winter. The marking here is effected by means of a tiny bit of platinum, 7 mm. long, and 4 mm. broad, being thus about the size of the nail on the little finger, which is attached by a very fine platinum wire to the fat fin of the big fish and the tail of the smaller ones. The piece has a number stamped on it, which corresponds with one in a "log" giving all the particulars as to the date the fish was marked, its weight, size, &c.

In order to encourage fishermen to be on the look-out for these marked fish, the inspector offers a reward of two shillings and sixpence for each mark forwarded to him, if accompanied with precise information as to the spot and date when it was taken, the length and breadth of the fish, and its weight.

As these researches will tend greatly to ascertain the habits and migrations of *Salmonidæ*, the result will be watched with interest.

THE TRINITY HOUSE EXPERIMENTS ON LIGHTHOUSE ILLUMINANTS

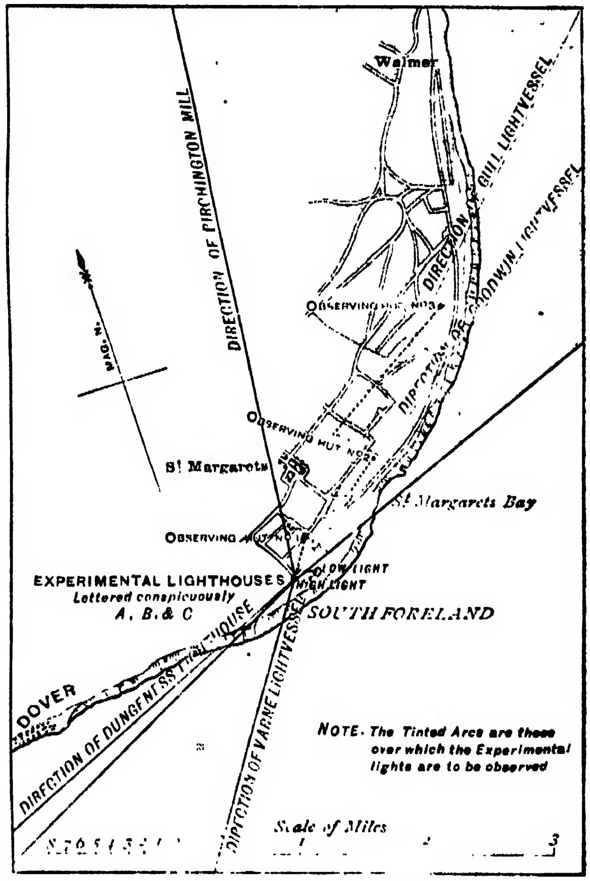
THE great advances made during the past few years in the science of illumination have rendered it desirable, or rather absolutely necessary, that experiments should be undertaken with a view to the determination of the advantages and disadvantages attending the use of different illuminants in lighthouses. With this view the Corporation of Trinity House have commenced a series of experiments at the South Foreland.

There are at present on the South Foreland two lighthouses, known as the high light and low light, and both of these are illuminated by electricity. Near these, three experimental lighthouses have been erected for use with the electric light, with gas and with oil respectively. The electric apparatus consists of three arc lamps and three magneto-electric machines made by Baron de Meritens. The lamps are placed one above the other in the tower. The carbons being used are "compound carbons," made up of many small rods of carbon of square section, coated with copper, and Siemens's "core-carbons," made of gas-carbon, with a central rod of graphite. When worked up to their full power, each lamp is estimated to be capable of giving a light equal to 30,000 candles.

The second tower is fitted up with Mr. Wigham's gas-burners. To supply the burners a small gasworks, fitted with retorts, purifiers, and a gasholder capable of holding about 5000 cubic feet, have been erected near by. The tower contains four burners, one above the other, each burner consisting of concentric rings of jets. The total number of jets on each burner is 108, making a total on the four burners of 432 jets; but the outer rings may be removed when less light is required: so that each burner may be used with 28, 48, 68, 88, or 108 jets. A talc chimney above the flame produces the necessary draught; no glass or talc is placed over the most luminous portion of the flame.

The intensity of the light when all the jets on all four burners are used is stated by the inventor to be equal to 12,000 candles. The third tower is for the present devoted to the oil and gas-burners invented by Sir James Douglass. The oil is supplied from a tank to the burners under a slight pressure. One oil-burner has six concentric wicks, and has a power of 720 candles; a second has seven wicks and a power of 1000 candles. There are three burners in the tower, placed one above the other. Each tower is provided with lenses both for revolving and for fixed lights. The highest power of the gas tower is a quadriform light, of the other towers a triform light. Besides the illuminants already mentioned, there are gas-burners from the Sugg and from the Siemens Companies, which will be tested in the lighthouse towers.

For observing the lights and testing them, a line of



Local Map for Observations on Land.

observation has been measured out in the direction of Deal, and three huts have been erected at a distance of ½ mile, 1¼ mile, and 2½ miles respectively from the towers. These huts are fitted up as photometric observatories. The lights are focussed on one of the huts, and they are then measured in all conditions of weather by means of the pentane unit of light devised by Mr. Vernon Harcourt. When the weather is too thick to allow of direct comparison with the unit, the lights are compared one with another by means of a polariscope-photometer, in which the ordinary image of one light is brought to equality by means of a Nicol prism with the extraordinary image of another light. In ordinary weather a ray from the lighthouse tower enters a hole in a shutter and falls

on a portion of a paper disk: a contiguous portion of the disk is illuminated by the pentane candle fixed on one side of the opening in the shutter. The disk can be moved on a trolley to and fro until equality of illumination is reached, when its distance from the candle is measured. This measure and the known distance of the observatory from the lighthouse give the necessary data for determining the illuminating power of the light. By these measurements, taken at different distances in various states of the atmosphere, the penetrative power of the several illuminants will be determined. For instance, in very clear weather the electric light may give twenty times the light of the oil light; a slight haze comes on and the electric light is found to be only ten times as bright. It has suffered in a greater ratio than the other. A mist blows by the towers, and the superiority of the electric light becomes less and less marked: before the lights are finally obscured the superiority has vanished. It need hardly be stated that this question of penetration is the most important point the Trinity House are called on to settle.

The principle of superposition of lights also raises an interesting point. When two lights are placed close together they can be seen at a greater distance than one light. Up to what point will this increase of range continue on multiplying the lights—without altering the intrinsic brightness of each? It may be that in thick weather the eye can detect a large area of low illumination better than a smaller area of higher illumination; and it may be that the electric light with its smaller lenses suffers from this reason in comparison with the oil and gas lights with their larger lenses.

We hope that the experiments will not be discontinued before these points have been thoroughly sifted, as they only can be satisfactorily, on the actual working scale.

We may add that the electric machines and cables are being tested by Prof. Grylls Adams, and the photometric observations taken by Mr. Harold Dixon. Mr. Vernon Harcourt is appointed to watch the experiments generally and report to the Board of Trade.

We give a plan of the district showing the point of observation, which includes the coast-guard stations and light-ships in the vicinity.

THE INTERNATIONAL CONFERENCE ON EDUCATION

THE Conference which was held at the Health Exhibition last week has achieved a remarkable success. It was attended by upwards of a thousand persons, including many of the leading teachers in English, Scotch, and continental schools, University professors, statesmen, managers of schools, and others interested in different ways in the subject of education. The interest was so well sustained that all four sections were more crowded on the last day than the first, and very general regret was expressed that the Conference should close so soon. Two circumstances mainly contributed to this result. The president, Lord Reay, by his tact and courtesy, his knowledge of foreign languages, and his cosmopolitan experience was singularly qualified, both to obtain from different continental States their most fitting representatives, and to give to these representatives when they arrived appropriate tasks and a worthy welcome. And Lord Reay was helped in the task of organising the Conference by a small but efficient committee, by whom during several previous months the work of selecting the readers of papers had been sedulously pursued. Unless pains had been taken in relation to each subject of discussion to secure that it should be initiated by a person who spoke upon it with some authority, and special knowledge, the result would have been far less satisfactory.

The Conference sat in four sections, which were at work simultaneously during five days. The first of these was devoted mainly to the consideration of questions relating to elementary education. The best and most fruitful subjects of discussion here were the Kindergarten, physical training, and the right way of inspecting, examining, or otherwise testing the work of pupils. Fröbel's principles, which have done so much to transform the system of training very young children in England, in Belgium, and in France, were expounded with much fulness of knowledge and felicity of illustration by some of Fröbel's own countrymen and disciples, as well as by ladies who have in England qualified themselves by special sympathy and knowledge to become his exponents. Closely akin to this subject were the topics of gymnastic and physical training, the better construction of schools and school apparatus, and the indirect effect of pictorial or other decorations in improving the taste and cultivating the imagination, and of increasing the scholars' interest in their work. The Swedish and other systems of bodily exercise, and the means of sense training by music and by object lessons were well discussed. On the general subject of the organisation of elementary education, which was debated in a crowded audience under the presidency of the Vice-President of the Council, the results were somewhat disappointing. Some of the teachers took the opportunity of the presence of their official chief to urge the demand with which the public have been long familiar, for grants of public money on easier conditions, and for the abandonment of the principle of payment by results. But no other practical method of distributing the public money was suggested, and it was generally felt that the Vice-President had an easy victory over those who sought to attack the principles of the recently-modified Code. A more important subject was raised in the animated debate on the inspection and examination of schools, which was rendered more apposite at the moment by the appearance of the recommendations of the Select Committee of the House of Commons, recommending that there should be in England a Minister of Public Instruction, and that he should have *inter alia* the duty of inspecting and annually reporting on the endowed secondary schools. It was perceived that this was a step of considerable moment and significance. Under the Act of 1869 endowed schools have been re-organised, and their governing bodies and schemes of study re-constituted. But neither the Commissioners who administer that Act, nor the public, know anything of the way in which those schemes are carried out, nor of the actual performances of the schools from year to year. There was among the larger number of earnest speakers on this point, a very general agreement on two points: first that some such public supervision over the reformed foundations was absolutely necessary, in order to keep them efficient; and secondly, that as there would be in this case no grant to administer, there would not be, as in elementary schools, any need to formulate conditions as to instruction, but simply to inquire in every case what the endowed school professed to do, and to see how far it had realised its own ideal. It is rather for the purpose of knowing what the schools are doing, than for that of imposing upon them by authority any theory or official ideal that State supervision seems to be demanded in regard to endowed schools.

In the second of the sections the principal topics of discussion were connected with scientific, technical, and artistic instruction. The fact that the Conference held its sittings in the new and beautiful buildings recently erected for the City and Guilds of London Technical Institute, naturally excited special interest, and awakened discussion as to the place which the physical sciences ought to hold in general education, as well as the special uses to which the Institute might be put in connection with the improvement of handicrafts and skilled trade. Mr. Magnus, Prof. Armstrong, Mr. Sparkes, and other

authorities whose names are associated with the improved teaching of science or of art in this country, were enabled to compare notes with professors of similar subjects from France and the United States, and some useful results were arrived at. In one special department of this Section, the agriculturists, under the presidency of Lord Fortescue and Sir Thomas Acland, held several long and animated discussions on the better teaching of agricultural science, on farm schools, and on the right education of boys intended to be farmers. In another department the subject of school museums was brought forward in an interesting paper by Dr. Jex-Blake of Rugby, and divers subsidiary aids to school instruction, such as field excursions, organised visits to factories, museums, and other places of interest, were suggested or described. Some of the more skilled and earnest of the elementary teachers, who, by their own personal influence, have secured the co-operation of their scholars in the formation of school museums illustrative of the flora, fauna, history, or industry of particular districts, gave interesting accounts of their plans and of the practical results which attended them; and from France and Belgium, and particularly from Liverpool, remarkable testimony was produced as to the success which had attended school savings' banks, and the influence they had exercised on the children and their parents.

The third section was mainly concerned with Universities and their relation to secondary instruction on the one hand, and to the liberal professions on the other. Profs. Morley, Fleeming Jenkin, and Seeley discoursed severally on those parts of the University curriculum with which their own names are most prominently associated, while the legal and theological aspects of the University question were discussed by Sir C. Bowen and Prof. Lorimer, by Cardinal Manning and Dr. Wace. The chief interest of this section, however, lay in that department in which the proper relation between the teaching and the examining functions of a University were examined by Sir George Young and others. The status of the present University of London was regarded by many speakers as unsatisfactory, notwithstanding the searching and effective character of its examinations, and the stimulating influence which its regulations have had upon the education of students in all parts of the country. A strong wish was expressed by many speakers, that the greatest city in the world should possess a teaching University, rather than a mere examining Board; and that some means should be found of co-ordinating all the higher agencies now at work in the metropolis in such a way as to constitute a London University of a new and nobler type. The duties of the Universities to our Indian Empire were well urged upon the Conference by Prof. Monier Williams; and the whole subject of the relations of the Universities to the education of women was debated in a crowded room and with great animation and interest, *apropos* of a paper by Mrs. Henry Sidgwick, whose own valuable services at Newnham have given her a special claim to speak with authority on such a topic.

The fourth section had a somewhat miscellaneous programme, but may be briefly described as concerned with problems connected with secondary and intermediate education. The first of these problems was the training of teachers, and the best means of securing for secondary schools a supply of teachers, qualified in respect to their knowledge of the theory and practice of their art, not less satisfactorily than the trained and certificated teachers of the elementary schools are, relatively to the humbler work which they have to do. Mr. Quick, Mr. Storr, Professors Laurie and Meiklejohn, and others who have made this a special subject of investigation, were enabled to throw much light on the recent efforts of the Universities to provide instruction in the art and philosophy of teaching, and to give professional certificates to persons qualified to receive them. It was manifest, however, from this discussion, that the one great hindrance in the way of such progress was the practical disbelief among the head-masters in the value of special professional training. Were it once understood that over and above the possession of a good University degree a head-master in search of an assistant would require, or would even *cæteris paribus* prefer that the candidate should show a knowledge of the principles of teaching or the literature of his profession, the arrangements of the Universities for imparting such knowledge would soon produce good fruit. At present, however, the teacher's diplomas issued by the Universities of Cambridge and London appear to possess but little market value in the public schools. It was shown, however, that in girls' schools of the highest class the work of professional training was much more keenly appreciated; and that among the foremost women engaged in the teaching profession, the strongest interest had been taken not only in the proposals of the Universities, but also in the Bishopsgate Training College, the Lectures of the College of Preceptors, and other public measures for ensuring specific instruction in the art and mystery of their craft for the skilled teachers of the future. One of the warmest, and at the same time one of the ablest debates in the Conference concerned the possible future relations of the State to secondary and higher education. Mr. Lyulph Stanley contended strongly for some public provision for the establishment of good secondary schools where they are deficient, and sketched out a plan which had evidently been thought out with some care, for the creation of such schools by means of rates, and for the supervision of such schools by local bodies having the public confidence. Canon Daniel, on the other hand, contended with much ability in favour of absolute freedom for local and religious bodies in the matter of secondary instruction, and against any attempt on the part of the State to initiate or control it. He pointed out, with considerable force, the remarkable success of the Girls' Public Day Schools Company, and remarked on the rapid growth of other agencies of a similar kind for supplying good middle-class schools, and for adapting the supply to the religious, social, and educational wants of different classes of the community.

Perhaps, on the whole, the most striking feature of the Conference, in the eyes of the numerous foreigners who were present and took part in the proceedings, was the remarkable interest evinced in the improved education of women; the variety of new fields now opening to their intelligence, activity, and public usefulness, and the number of ladies who took an active and effective share in the various discussions. Another point of special interest was the international character of the whole Conference, and the warm welcome with which the experience of experts from France, Belgium, Switzerland, Germany, and the United States, was received in all the sections. There has probably never been in the history of education in this country a gathering which afforded such an excellent opportunity for the interchange of opinions and suggestions between English and foreign teachers. And the executive of the Exhibition may well be congratulated on having added to their other successes the completion of a work of pre-eminent and far-reaching usefulness—a Conference which, for the ability of those who took part in it, for the high tone and courtesy of its discussions, and for the fruitfulness of its practical suggestions, has left an enduring and most pleasing impression on all who took part in it.

Among the subsidiary features of the Conference not the least useful were the visits organised by the Committee to some of the more characteristic and important of English schools. The most successful of these visits was that paid to the new buildings of St. Paul's School at West Kensington, which, though not yet occupied by the scholars, is now nearly complete in all its appointments. The party, nearly fifty in number, consisted largely of

foreign teachers from various countries. They were conducted over Mr. Waterhouse's costly and beautiful building by the Clerk of the Works and by a member of the governing body, and evinced much interest in observing all the latest improvements in school construction and fittings, and in inspecting the library, laboratories, lecture-rooms, and the ample appliances for physical training.

It is understood that the results of the Conference, the text of the papers, and a summary of the discussions will shortly appear in four or five volumes.

THE VOYAGE OF THE "VETTOR PISANI"

KNOWING how much NATURE is read by all the naturalists of the world, I send these few lines, which I hope will be of some interest.

The Italian R.N. corvette *Vettor Pisani* left Italy in April 1882 for a voyage round the world with the ordinary commission of a man-of-war. The Minister of Marine, wishing to obtain scientific results, gave orders to form, when possible, a marine zoological collection, and to carry on surveying, deep-sea soundings, and abyssal thermometrical measurements. The officers of the ship received their different scientific charges, and Prof. Dohrn, director of the Zoological Station at Naples, gave to the writer the necessary instructions for collecting and preserving sea animals.

At the end of 1882 the *Vettor Pisani* visited the Straits of Magellan, the Patagonian Channels, and Chonos and Chiloe Islands; we surveyed the Darwin Channel, and following Dr. Cuningham's work (who visited these places on board H.M.S. *Nassau*), we made a numerous collection of sea animals by dredging and fishing along the coasts.

While fishing for a big shark in the Gulf of Panama during the stay of our ship in Taboga Island one day in February, with a dead calm, we saw several great sharks some miles from our anchorage. In a short time several boats with natives went to sea, accompanied by two of the *Vettor Pisani's* boats.

Having wounded one of these animals in the lateral part of the belly, we held him with lines fixed to the spears; he then began to describe a very narrow curve, and irritated by the cries of the people that were in the boats, ran off with a moderate velocity. To the first boat, which held the lines just mentioned, the other boats were fastened, and it was a rather strange emotion to feel ourselves towed by the monster for more than three hours with a velocity that proved to be two miles per hour. One of the boats was filled with water. At last the animal was tired by the great loss of blood, and the boats assembled to haul in the lines and tow the shark on shore.

With much difficulty the nine boats towed the animal alongside the *Vettor Pisani* to have him hoisted on board, but it was impossible on account of his colossal dimensions. But, as it was high water we went towards a sand beach with the animal, and we had him safely stranded at night.

With much care were inspected the mouth, the nostrils, the ears, and all the body, but no parasite was found. The eyes were taken out and prepared for histological study. The set of teeth was all covered by a membrane that surrounded internally the lips; the teeth are very little and almost in a rudimental state. The mouth, instead of opening in the inferior part of the head, as in common sharks, was at the extremity of the head; the jaws having the same bend.

Cutting the animal on one side of the backbone we met (1) a compact layer of white fat 20 centimetres deep; (2) the cartilaginous ribs covered with blood vessels; (3) a stratum of flabby, stringy, white muscle, 60 centimetres high, apparently in adipose degeneracy; (4) the stomach.

By each side of the backbone he had three chamferings, or flutings, that were distinguished by inflected interstices. The colour of the back was brown with yellow spots that became close and small towards the head so as to be like marble spots. The length of the shark was 8·90 m. from the mouth to the *pinna caudalis* extremity, the greatest circumference 6·50 m., and 2·50 m. the main diameter (the outline of the two projections is made for giving other dimensions).

The natives call the species *Tintorera*, and the most aged of the village had only once before fished such an animal, but smaller. While the animal was on board we saw several *Remora* about a foot long drop from his mouth; it was proved that these fish lived fixed to the palate, and one of them was pulled off and kept in the zoological collection of the ship.

The *Vettor Pisani* has up to the present visited Gibraltar, Cape Verde Islands, Pernambuco, Rio Janeiro, Monte Video, Valparaiso, many ports of Peru, Guayaquil, Panama, Galapagos Islands, and all the collections were up to this sent to the Zoological Station at Naples to be studied by the naturalists. By this time the ship left Callao for Honolulu, Manila, Hong Kong, and, as the *Challenger* had not crossed the Pacific Ocean in these directions, we made several soundings and deep-sea thermometrical measurements from Callao to Honolulu. Soundings are made with a steel wire (Thomson system) and a sounding-rod invented by J. Palumbo, captain of the ship. The thermometer employed is a Negretti and Zambra deep-sea thermometer, improved by Captain Maguaghi (director of the Italian R.N. Hydrographic Office).

With the thermometer wire has always been sent down a tow-net which opens and closes automatically, also invented by Captain Palumbo. This tow-net has brought up some little animals that I think are unknown.

Honolulu, July 1 G. CHIERCHIA

The shark captured by the *Vettor Pisani* in the Gulf of Panama is *Rhinodon typicus*, probably the most gigantic fish in existence. Mr. Swinburne Ward, formerly Commissioner of the Seychelles, has informed me that it attains to a length of 50 feet or more, which statement was afterwards confirmed by Prof. E. P. Wright. Originally described by Sir A. Smith from a single specimen which was killed in the neighbourhood of Cape Town, this species proved to be of not uncommon occurrence in the Seychelle Archipelago, where it is known by the name of "Chagrin." Quite recently Mr. Haly reported the capture of a specimen on the coast of Ceylon. Like other large sharks (*Carcharodon rondeletii*, *Selache maxima*, &c.), Rhinodon has a wide geographical range, and the fact of its occurrence on the Pacific Coast of America, previously indicated by two sources, appears now to be fully established. T. Gill in 1865 described a large shark known in the Gulf of California by the name of "Tiburon ballenas" or whale-shark, as a distinct genus—*Micristodus punctatus*—which, in my opinion, is the same fish. And finally, Prof. W. Nation examined in 1878 a specimen captured at Callao. Of this specimen we possess in the British Museum a portion of the dental plate. The teeth differ in no respect from those of a Seychelles Chagrin; they are conical, sharply pointed, recurved, with the base of attachment swollen. Making no more than due allowance for such variations in the descriptions by different observers, as are unavoidable in accounts of huge creatures examined by some in a fresh, by others in a preserved state, we find the principal characteristics identical in all these accounts, viz. the form of the body, head, and snout, relative measurements, position of mouth, nostrils and eyes, dentition, peculiar ridges on the side of the trunk and tail, coloration, &c. I have only to add that this

shark is stated to be of mild disposition and quite harmless. Indeed, the minute size of its teeth has led to the belief in the Seychelles that it is a herbivorous fish, which, however, is not probable.

ALBERT GÜNTHER

Natural History Museum, July 30

PYROMETERS

THE accurate measurement of very high temperatures is a matter of great importance, especially with regard to metallurgical operations; but it is also one of great difficulty. Until recent years the only methods suggested were to measure the expansion of a given fluid or gas, as in the air pyrometer; or to measure the contraction of a cone of hard, burnt clay, as in the Wedgwood pyrometer. Neither of these systems were at all reliable or satisfactory. Lately, however, other principles have been introduced with considerable success, and the matter is of so much interest not only to the practical manufacturer but also to the physicist, that a sketch of the chief systems now in use will probably be acceptable. He will thus be enabled to select the instrument best suited for the particular purpose he may have in view.

The first real improvement in this direction, as in so many others, is due to the genius of Sir William Siemens. His first attempt was a calorimetric pyrometer, in which a mass of copper at the temperature required to be known is thrown into the water of a calorimeter, and the heat it has absorbed thus determined. This method, however, is not very reliable, and was superseded by his well-known electric pyrometer. This rests on the principle that the electric resistance of metal conductors increases with the temperature. In the ca e of platinum, the metal chosen for the purpose, this increase up to 1500° C. is very nearly in the exact proportion of the rise of temperature. The principle is applied in the following manner:—A cylinder of fireclay slides in a metal tube, and has two platinum wires 100th of an inch in diameter wound round it in separate grooves. Their ends are connected at the top to two conductors, which pass down inside the tube and end in a fireclay plug at the bottom. The other ends of the wires are connected with a small platinum coil, which is kept at a constant resistance. A third conductor starting from the top of the tube passes down through it and comes out at the face of the metal plug. The tube is inserted in the medium whose temperature is to be found, and the electric resistance of the coil is measured by a differential voltameter. From this it is easy to deduce the temperature to which the platinum has been raised. This pyrometer is probably the most widely used at the present time.

Tremeschini's pyrometer is based on a different principle, viz. on the expansion of a thin plate of platinum, which is heated by a mass of metal previously raised to the temperature of the medium. The exact arrangements are difficult to describe without the aid of drawings, but the result is to measure the difference of temperature between the medium to be tested and the atmosphere at the position of the instrument. The whole apparatus is simple, compact, and easy to manage, and its indications appear to be correct at least up to 800° C.

The Trampler pyrometer is based upon the difference in the coefficients of dilatation for iron and graphite, that of the latter being about two-thirds that of the former. There is an iron tube containing a stick of hard graphite. This is placed in the medium to be examined, and both lengthen under the heat, but the iron the most of the two. At the top of the stick of graphite is a metal cap carrying a knife-edge, on which rests a bent lever pressed down upon it by a light spring. A fine chain attached to the long arm of this lever is wound upon a small pulley; a larger pulley on the same axis has wound upon it a second chain, which actuates a third pulley on the axis of the indicating needle. In this way the relative dilatation of the graphite is sufficiently magnified to be easily visible.

A somewhat similar instrument is the Gauntlett pyrometer, which is largely used in the north of England. Here the instrument is partly of iron, partly of fireclay, and the difference in the expansion of the two materials is caused to act by a system of springs upon a needle revolving upon a dial.

The Ducomet pyrometer is on a very different principle, and only applicable to rough determinations. It consists of a series of rings made of alloys which have slightly different melting-points. These are strung upon a rod, which is pushed into the medium to be measured, and are pressed together by a spiral spring. As soon as any one of the rings begins to soften under the heat, it is squeezed together by the pressure, and, as it melts, it is completely squeezed out and disappears. The rod is then made to rise by the thickness of the melted ring, and a simple apparatus shows at any moment the number of rings which have melted, and therefore the temperature which has been attained. This instrument cannot be used to follow variations of temperature, but indicates clearly the moment when a particular temperature is attained. It is of course entirely dependent on the accuracy with which the melting-points of the various alloys have been fixed.

Yet another principle is involved in the instrument called the Thalpotasimeter, which may be used either with ether, water, or mercury. It is based on the principle that the pressure of any saturated vapour corresponds to its temperature. The instrument consists of a tube of metal partly filled with liquid, which is exposed to the medium which is to be measured. A metallic pressure gauge is connected with the tube, and indicates the pressure existing within it at any moment. By graduating the face of the gauge when the instrument is at known temperatures, the temperature can be read off directly from the position of the needle. From 100° to 220° F. ether is the liquid used, from thence to 680° it is water, and above the latter temperature mercury is employed.

Another class of pyrometers having great promise in the future is based on what may be called the "water-current" principle. Here the temperature is determined by noting the amount of heat communicated to a known current of water circulating in the medium to be observed. The idea, which was due to M. de Saintignon, has been carried out in its most improved form by M. Boulier. Here the pyrometer itself consists of a set of tubes one inside the other, and all inclosed for safety in a large tube of fireclay. The central tube or pipe brings in the water from a tank above, where it is maintained at a constant level. The water descends to the bottom of the instrument and opens into the end of another small tube called the explorer (*explorateur*). This tube projects from the fireclay casing into the medium to be examined, and can be pushed in or out as required. After circulating through this tube the water rises again in the annular space between the central pipe and the second pipe. The similar space between the second pipe and the third pipe is always filled by another and much larger current of water which keeps the interior cool. The result is that no loss of heat is possible in the instrument, and the water in the central tube merely takes up just so much heat as is conducted into it through the metal of the explorer. This heat it brings back through a short indiarubber pipe to a casing containing a thermometer. This thermometer is immersed in the returning current of water and records its temperature. It is graduated by immersing the instrument in known and constant temperatures, and thus the graduations on the thermometer give at once the temperature, not of the current of water, but of the medium from which it has received its heat.

in order to render the instrument perfectly reliable, all that is necessary is that the current of water should be always perfectly uniform, and this is easily attained by fixing the size of the outlet once for all, and also the level of water in the tank. So arranged, the pyrometer works with great regularity, indicating the least variations of temperature, requiring no sort of attention, and never suffering injury under the most intense heat; in fact the tube, when withdrawn from the furnace, is found to be merely warm. If there is any risk of the instrument getting broken from fall of materials or other causes, it may be fitted with an ingenious self-acting apparatus shutting off the supply. For this purpose the water which has passed the thermometer is made to fall into a funnel hung on the longer arm of a balanced lever. With an ordinary flow the water stands at a certain height in the funnel, and, while this is so, the lever remains balanced; but if from any accident the flow is diminished, the level of the water in the funnel descends, the other arm of the lever falls, and in doing so releases two springs, one of which in flying up rings a bell, and the other by detaching a counterweight closes a cock and stops the supply of water altogether.

It will be seen that these instruments are not adapted for shifting about from place to place in order to observe different temperatures, but rather for following the variations of temperature at one and the same place. For many purposes this is of great importance. They have been used with great success in porcelain furnaces, both at the famous manufactories at Sèvres and at another porcelain works in Limoges. From both these establishments very favourable reports as to their working have been received. W. R. BROWNE

THE AGRICULTURAL INSTITUTE OF BEAUVAIS

WE have already referred to the interesting collection exhibited in the Technical School at the Health Exhibition by the Brothers of the Christian Schools. One of the most instructive of their specimen museums is that from their Agricultural Institute at Beauvais.

This Institute was founded in 1855, the late Prince Consort being one of its first patrons. Recently the Agronomical Society of France have extended to it an encouraging hand.

Candidates for admission to the school must be at least sixteen years of age, and must give evidence, either by certificates obtained or by a preliminary examination, of their having successfully studied the recognised branches of a good modern education. The course of instruction extends over a period of three years, and is intended to prepare young men to manage and develop estates and direct all farming operations. Special provision is made, in the third year, for those who wish to qualify themselves for agricultural professorships. The syllabus of subjects is framed by a Board appointed by the prefect of the *département*, and consists of the Director and Professors of the Institute, of the Professor of Agriculture, and the Veterinary Surgeon of the *département*, as also of three other members.

The subjects for the first year are: French language, book-keeping and commercial subjects, elementary algebra and geometry, the fundamental principles of agriculture, rural law and engineering, general zoology, arboriculture, horticulture, physics, chemistry, and linear drawing.

In the second year the students follow more advanced courses of agriculture, zoology, botany, entomology, geology, surveying, levelling, physics, general and analytical chemistry, rural law and engineering, linear drawing, arboriculture, and horticulture.

The instruction for the last year comprises agriculture, arboriculture, horticulture, analytical chemistry, botany, geology, entomology, applied mathematics and mechanics, and architectural drawing.

Science teaching, to be of any use, must be practical; the authorities of the Agricultural Institute, fully convinced of this, attach great importance to laboratory and field work. In the physical laboratory, the work is exclusively of a demonstrational kind, the students not being required to test the accuracy of their knowledge or their familiarity with instruments by the actual and precise measurement of physical constants. Nor do such measurements appear necessary for the object in view. It is, of course, quite different with chemistry, where skill in quantitative analysis is of the highest value to any one who intends to direct the agricultural interests of a district. The students are consequently trained with much care in those branches of analytical chemistry which bear directly upon the science of agriculture. The study of botany, geology, and entomology is encouraged and stimulated by frequent excursions to the neighbouring country, the specimens brought back being compared, classified, and minutely described in appropriate language.

The school has also a model farm of 325 acres, in which the principal operations of farming are extensively carried on. The students visit this farm at stated hours every week; they are familiarised with the chief implements and agricultural appliances, and are required to take part in all the regular work that may be going on.

The Professors have set aside a number of acres for experimenting upon the conditions most favourable to the growth of the principal cereals. These comparative studies are carried out with the assistance of the students mainly for the purpose of showing them how to practically initiate a scientific investigation of an agricultural nature. The results of these studies are fully described in the *Annales de l'Institut agricole*, a yearly publication of considerable merit. A valuable synopsis of the results obtained by the Director of the School, Brother Eugene, will be found in the Educational Section of the International Health Exhibition, Room 5.

From a recent report, we find that there have been, this year, under cultivation no less than sixty-five kinds of wheat, twenty of oats, ten of barley, eight of rye, besides fields of potatoes, beetroot, cabbage, &c. There are also pasture lands for sheep and cows, and a well-stocked poultry yard.

At the end of each year the students are put through a practical examination, when they are expected to give satisfactory evidence of their competency to deal with the general working of the farm. It is also required by the programme of the Institute that the students shall visit exhibitions of an agricultural character which may be held in the vicinity, and attend with their Professors certain markets and sales of live stock.

The attention of the students is maintained and quickened by requiring them to write, with considerable care, notes of all their courses, as well as detailed reports of what they may have seen in their visits or met with in their excursions. Several volumes of these reports, notes, and theses, together with typical herbaria, specimens of grain and seeds, may be seen in the Exhibition, Room 5.

Besides superintending the museum and giving instruction in the laboratories, the Brothers teach drawing, physics, chemistry, botany, geology, zoology, &c., leaving such subjects as rural jurisprudence and engineering, agriculture, and the like to other eminent professors.

IS SALPA AN EXAMPLE OF ALTERNATION OF GENERATIONS?

THE chances against the accidental discovery of a great natural law are so great that we cannot feel surprise that naturalists are slow to believe that Salpa,

the animal in which Chamisso discovered alternation of generations, is not an example of alternation.

The historical associations which render the life-history of Salpa so interesting to the naturalist have induced me to restate briefly my reasons for believing that the solitary Salpa is a female and the chain Salpa a male; since a recent contributor to NATURE (" Recent Morphological Speculations," by R. N. G., in NATURE, May 15, p. 67) rejects my observations for reasons which a little examination will show to be inconclusive.

The author characterises my opinion as " Brooks' theory," but it is neither a theory, nor was I the first to describe the phenomenon in question. Embryological observations by Kowalevsky must be received by all

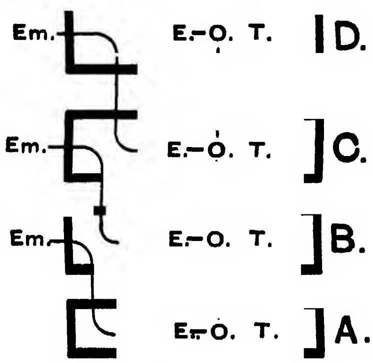


Fig. 1

naturalists with the greatest respect, and I therefore call the attention of R. N. G. to the fact that this great observer published, while my first paper was in the press, the following account of the life-history of Salpa (see *Arch. f. Mik. Anat.* xi. 604):—" Bei den Salpen giebt es bekanntlich zwei Generationen, in der einen entwickelt sich der aus vielen eikeimen bestehende Eierstock, welcher in den Stolo hineingeht, und sich hier zu je einem Eie vertheilt, sodann die einzelnen Knospen resp. Kettensalpen in welchen weiter aus diesem Eie ein Embryo entsteht, wieder mit einem aus mehreren Eikeimen bestehende Eierstock."

No one will question the statement that the animal in whose body an ovum is produced is the mother of the

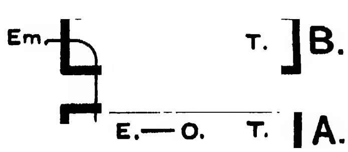

Fig. 2

embryo to which this ovum gives rise, and if the egg which is fertilised in the body of the chain Salpa is developed, as Kowalevsky and I have stated, in the body of the solitary Salpa, the latter is certainly a female, and as no one has ever observed the production by a chain Salpa of more than one embryo, either from an egg or by budding, there is no true alternation of generations.

This view is in no sense a " morphological speculation," nor should it be spoken of as " Brooks' theory." It is either an observed fact or an erroneous statement, and its untruth can be proved only by observation.

R. N. G. lays much stress upon the life-history of Pyrosoma, a closely related but less modified form, and regards it as an " indirect negation " of my statement that the solitary Salpa is a female, and the chain Salpa a male. Our knowledge of Pyrosoma and of other Tunicates certainly leads us to believe that Salpa is the descendant of a hermaphrodite ancestor, but it proves nothing more.

The fact that nearly all the Arthropods are bisexual does not disprove the hermaphroditism of Balanus. It simply shows that Balanus is the modified descendant of bisexual ancestors.

While the life-history of Pyrosoma cannot be quoted to disprove the statement that the solitary Salpa has an ovary, it can help us to understand the way in which the present life-history of Salpa has been acquired, and thus show that my own view is not very anomalous after all.

As the phenomena are very complex, I have attempted to exhibit the leading features by diagrams, and Fig. 1 shows the points of greatest importance in the life-history of Pyrosoma.

The egg gives rise, by a process which does not here concern us, to several sexual animals, one of which is represented by A in Fig. 1. It has a testis, T, and an ovary, O, which consists in part of " generative blastema," and, in part, of ova in various stages of growth. It is, therefore, a hermaphrodite. One of the ova, E, is very much larger than any of the others. This hermaphrodite,

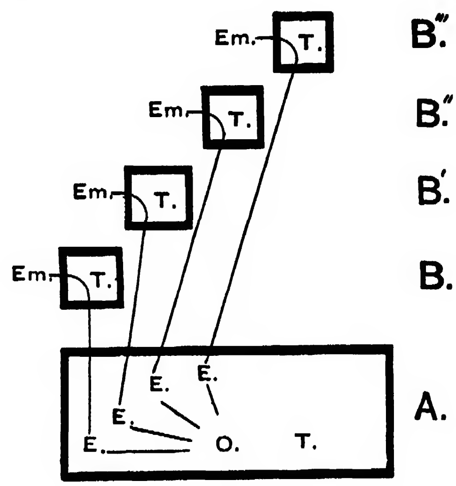

Fig. 3

A, produces a second, B, by budding, and during this process part of the " generative blastema " from the ovary of A passes into the body of B, and forms its ovary, O, which here produces one fully developed ovum, E, and a number of small ones. As B has a testis, T, it is a hermaphrodite like A.

The single mature ovum, E, of A, also passes into the body of B, where it is fertilised and gives rise to an embryo, EM, which undergoes development within, and finally escapes from, the body of B, although A is its mother, because the egg which has produced it was formed in the ovary of A before the body of B was formed by budding.

B then gives rise by budding to C, and the single mature egg of B passes into the body of C, where it is fertilised, and gives rise to an embryo.

Part of the " generative blastema " of B's ovary passes into the body of the bud C, and becomes an ovary, O, which again gives rise to one mature ovum, E; and C produces another bud, D, and discharges into it one ripe ovum and part of the ovary in the same way, and so on indefinitely. As C and D have testes like A and B, they are all hermaphrodite.

After the bud B has become independent of A, another ovum is matured in A's ovary, another hermaphrodite bud

is produced, and so on indefinitely, and each hermaphrodite bud produces in succession an indefinite series of similar buds.

Now let us imagine a limit to this indefinite series of buds, and examine its effect.

Suppose that, while B retains its power to produce in succession an indefinite series of C's, the C's lose this power. As the function of the ovary of C is to provide the "generative blastema" for the ovaries of the series of D's, and to mature the eggs E, which are to be fertilised and developed within the bodies of the D's, it is plain that with the loss by the C's of the power to reproduce by

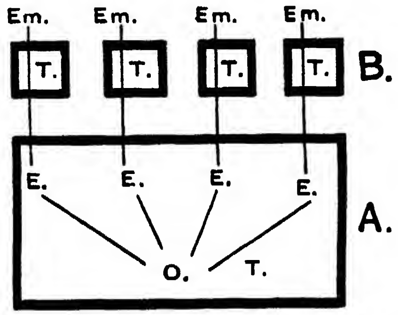

Fig. 4

budding, the ovary will be left without function, and we should therefore expect it to disappear. C would then become simply a male, but it would while young contain a single unfertilised egg, EM, derived from the ovary of B.

If the power to bud were lost by the first generation of buds, B, we should have the condition of things which is shown in Fig. 2, where the hermaphrodite A produces a male bud, B, and discharges the egg E into its body, there to be fertilised and developed into the embryo EM. A has, however, the power to repeat this process indefinitely, and to produce in succession a series of buds of the generation B, and the life-history is therefore now exactly shown in Fig. 3.

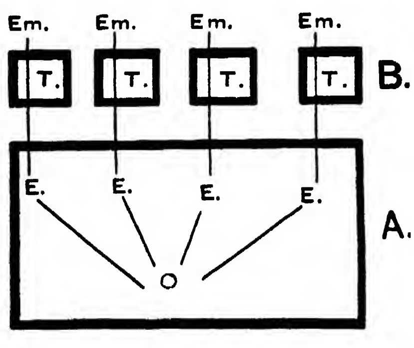

Fig. 5

Now suppose that, instead of appearing in succession, a number of buds of the generation B are formed at the same time, we shall then have the phenomena shown in Fig. 4, where a number of eggs, E, E, E, E, are matured simultaneously in the ovary, O, of the hermaphrodite A, and are discharged while still unfertilised into the bodies of the male buds, B, B, B, B, there to give rise to the embryos, EM, EM, EM, EM.

This is very nearly what we have in Salpa, where very many chain Salpæ are produced at one time. As these have no power to reproduce by budding, they have lost their ovaries, although each of them, when it is born, contains, like the buds of Pyrosoma, a single unfertilised egg, derived, according to my observations and those of Kowalevsky, and according to the analogy of Pyrosoma, from the ovary of the solitary Salpa A, Fig. 5.

The solitary Salpa is therefore a true female, and as it has lost the testis which, according to the analogy of Pyrosoma, its ancestors must have possessed, it is a true female and not a hermaphrodite.

We therefore have in place of the indefinite series of hermaphrodite buds of Pyrosoma, a single generation of male buds, each of which receives, like the buds of Pyrosoma, a single mature ovum from the ovary of its gemmiparous ancestor.

While the series of stages which are here described may not correspond exactly to the actual phylogeny of Salpa, it certainly shows that our knowledge of Pyrosoma cannot be quoted as an "indirect negation" of my view; for it shows that the analogy of Pyrosoma would lead us to look to the ovary of the solitary Salpa for the origin of the egg which is fertilised and developed within the body of the chain Salpa.

All observers agree that the so-called "ovary" of the chain Salpa consists of a single egg, which is fertilised while the animal which carries it is very young and almost embryonic, and all agree that normally no more eggs are produced by the chain Salpa. A "rudiment of an ovary, which only consists of one fully developed ovum" is certainly not an *ovary* at all, but an *ovum*, for the origin of which we must search elsewhere, and Kowalevsky's observation as well as my own show that it originates in the ovary of the solitary Salpa.

As all observers agree that the chain Salpa has a testis, and that it normally contains only one egg, it is certainly a male; and as all observers agree that the solitary Salpa has no testis, while Kowalevsky and I agree that it has an ovary, we must regard it as a female, and we therefore have, instead of an instance of alternation, a very remarkable example of sexual difference.

There seems to be only one way to escape this conclusion;—that is, by denying that the structure which Kowalevsky and I have described as an ovary is an ovary at all.

Salensky is an advocate of this view, and claims that my so-called ovary is simply a mass of embryonic cells destined to give rise to the branchial sacs, as well as the ovaries of the chain Salpæ, but I have shown in a recent paper in the *Zoologischer Anzeiger* that the branchial sacs of the chain Salpa originate from quite a different part of the stolon, and that the ovary contains cells which are in no sense embryonic or unspecialised, since they have all the characteristics of ova. In a paper which is now ready for publication, I shall give photographs of sections which prove this point beyond question.

R. N. G. gives, as another reason for rejecting my view, the fact that Salensky has found a second ovary in a chain Salpa.

This is clearly exceptional, for all observers agree that no such second ovary normally occurs, nor has Salensky given conclusive proof that the cells which he observed were ova at all, as he has not observed their development. Out of many thousand sections which I have examined, I have found three chain Salpæ which had received two ova from the ovary of the solitary Salpa instead of one, and if Salpa is descended from a form like Pyrosoma, it is quite possible that a chain Salpa may occasionally receive with its ovum part of the ovary, and that this may give rise to other ova, but the discovery of such an abnormal Salpa would not prove that the normal chain Salpa is hermaphrodite, even if it could be shown that these eggs completed their development and became embryos.

In conclusion, I wish to point out to R. N. G. that, inasmuch as the writer who attempts to generalise from the observed phenomena of science for the benefit of the public should use every precaution to insure accuracy in

the statement of facts, he will do well to examine his authority for his statements that I have called the *solitary* Salpa a *nurse;* that I have described a Cunina in which the "hydroid produces medusæ by gemmation;" and that I believe "that the solitary Salpa is hermaphrodite."

Baltimore, July 14 W. K. BROOKS

COLONIAL AND FOREIGN REPORTS

THE annual reports of colonial botanical gardens, Government plantations, museums, &c., form at the present day no inconsiderable item of the literature of scientific progress in different parts of the world which constantly crowd an editor's table. These records become, year after year, of increasing importance as well as of increasing bulk, and it is right that their contents should be better known, so that they may become useful, and this can only be done by a wide distribution of the reports themselves, and attention drawn to them by other publications.

Taking a few of these reports, which have recently come to hand, in the order of their issue, we first find one from Wellington, New Zealand, under the following title, "Eighteenth Annual Report on the Colonial Museum and Laboratory," together with the "Fourteenth Annual Report on the Colonial Botanic Garden, 1882-83." This Report treats of various branches of science, and, as might be expected, geology has its full share. In the observatory the principal work is said to have been the observation of the transit of Venus, Dr. Hector's account of his observation, which, he says, was written out within an hour after the transit, being given as an appendix. Under the head of Botanic Garden, after describing some successful experiments in planting wattles (species of *Acacia*), Dr. Hector refers to experiments in the cultivation of *Sorghum*, which, however, are said not to have been continued in the garden, but in the northern part of the colony, the results were very favourable, proving that quite as large a percentage of crystallisable sugar can be obtained in New Zealand as in America. "Recent improvements," it is said, "have been made in the machinery, and by the use of a vacuum evaporating pan all the causes of the former miscarriage in the production of the sugar appear to have been removed, so that there is every prospect of the growth of the *Sorghum* becoming an important industry in the north of New Zealand." A most interesting and important feature of the year is said to be the sudden expansion of the cultivation of hops in the colony. In Nelson it is shown that the cultivation has been most successful, and in the neighbourhood of Wellington the hop also grows well. The plants are subject more or less to attacks from the red spider and what is known as the plant louse, but they have not yet committed any great damage.

Mr. Morris's "Annual Report of the Public Gardens and Plantations for the year ended September 30, 1883," shows that the usual operations of the department have been fully maintained, while the "chief scientific work of the year has been connected with the collection and determination of numerous native plants of the island which have been added to the Department Herbarium, and the large addition of others to the growing collections." Referring to the attacks by insects on the sugar cane, Mr. Morris points out that the spasmodic or intermittent character of the attack is in accordance with their general habit in all parts of the world; "but," he says, "it is well for us to note their appearance and disappearance with great care, in order that we may thereby be prepared for their attacks, and reduce the amount of damage they do to our crops to a minimum."

The indiscriminate destruction of small birds in the island has attracted some attention, and measures have been suggested whereby it may be checked or perhaps stopped.

The mungoose, which has been imported from India to destroy rats on sugar estates, is stated to be increasing very rapidly, not only on sugar estates, but on the highest mountains along the shore, and even amidst swamps and lagoons. The sugar planters have greatly benefited by its introduction, rat-eaten canes being now scarcely known. The negro settlers and persons not connected with sugar estates complain of its ravages amongst their poultry, fruit, and vegetables. Mr. Morris says, however, that poultry is still fairly plentiful in country districts, and from his experience of the mungoose in confinement, the creature is not likely to eat either sugar cane, banana, or field vegetables, except under the influence of extreme hunger, which would not occur so long as there are rats, mice, lizards, and other small animals to feed on. "The mungoose is, however," Mr. Morris says, "disturbing greatly the distribution of animal life in the island; and the harmless yellow and other snakes, lizards, ground-hatching birds, the interesting cony, and many members of our indigenous fauna, are likely to become extinct at no distant period."

Under the head of cultivation and distribution of economic plants Mr. Morris reports progress in many new products. It is not encouraging, however, to find that the cultivation of ginger in Jamaica appears to be dying out, due "to the smaller yield of plants cultivated so persistently on the same land, to the uncertain nature of the crop, no less than the difficulty experienced in many districts in curing it properly." Jamaica ginger has hitherto held a prominent position in the market as to quality, and it is a pity that its reputation should become a thing of the past.

The next report before us is that of Dr. Schomburgk, and treats of the "Progress and condition of the Botanic Garden and Government plantations" at Adelaide, South Australia. A similar work seems to be going on here as at most other colonial gardens at the present time, namely, the distribution of native, and the acclimatisation of foreign plants, chiefly of economic value. The Gardens seem to be very popular, as well as the Museum of Economic Botany, which is a comparatively new institution to Adelaide. Two appendices are added to Dr. Schomburgk's report, one consisting of a "Catalogue of Plants added during 1883 to those under cultivation in the Botanic Garden," arranged according to their natural orders, and the other a "List of Palmæ, Bromeliaceæ, Filices, and Lycopodiaceæ, cultivated in the Botanic Garden." The report is illustrated by eight views in the Gardens.

A Report of the Committee of Management for 1883 of the Technological Industrial and Sanitary Museum of New South Wales shows that a great deal of progress has been made in extending the utility of the Museum during the year. The Museum, which seems to have been opened so recently as December last, bids fair to become of very great service to the colony. One paragraph in the Report says, "Special endeavours are being made to collect the raw products and samples illustrative of the industries and manufactures of the Australian colonies, and the Committee have already secured a considerable number of native vegetable and mineral products and a comprehensive series of specimens of wool."

The "Annual Report of the Royal Botanic Garden, Calcutta, for the year 1883-84," and that of the Government Cinchona Plantations in Bengal for the same period, are, as usual, very creditable to Dr. King as superintendent. Dr. King's reports are always concise and interesting records of admirable work both at the Botanic Garden and at the cinchona plantations, and those before us show that in the former a good deal of consideration has been paid during the year to the extension of plants of real commercial value, such, for instance, as paper materials, including the sabai grass (*Pollinia eriopoda*, Hance), and the

paper mulberry (*Broussonetia papyrifera*, Vent), also fibrous plants, including the Rhea, or China grass (*Boehmeria nivea*, W. and A.). Much progress has been made in arranging the specimens in the new building which has been providedf or the herbarium, and numerous contributions have been received both to the herbarium and to the gardens. In the Report on the cinchona plantations Dr. King gives details of the year's crop, of the expenditure for the year, and of the progress of the several forms or varieties. At the factory the total out-turns for the year was 8714 lbs. of febrifuge, 250 lbs. of which were of the new crystalline preparation, which closely resembles the ordinary febrifuge, but, on examination, the grains are seen to be small crystals; it differs, however, in constitution from the old febrifuge, inasmuch as it contains none of the amorphous alkaloid which is the ingredient in that preparation which causes the nausea which sometimes follows its administration. The efficiency of the staff both in the Calcutta Gardens and at the cinchona plantations is indicated by the testimony which Dr. King, with his usual frankness and consideration, bears to the ability of his subordinates.

From the Botanic Garden, Hong Kong, Mr. Charles Ford, the Superintendent of the Botanical and Afforestation Department, reports, under date April 30, 1884, of the department under his charge. A good many plants both of commercial and horticultural interest have been grown with more or less success, including the carob tree (*Ceratonia Siliqua*) of Southern Europe, the Chinese tea oil tree (*Camellia drupifera*), the Chinese varnish tree (*Aleurites vernicia*), and many others. A very interesting account of a visit to the Lo-fau-shan Mountains and a list of the plants collected is given in this Report.

NOTES

HER MAJESTY'S GOVERNMENT, on the recommendation of the Lords of the Committee of Council on Education, have given their adhesion to the International Geodetic Association, and have nominated the undermentioned gentlemen as delegates of the United Kingdom to the Association, viz.:—The Director-General of the Ordnance Survey (for the time being), Col. A. R. Clarke, R.E., F.R.S., the Astronomer-Royal, the Hydrographer of the Navy (for the time being), General J. T. Walker, R.E., C.B., F.R.S.

Two academic honours have recently, *Science* states, been conferred in the United States upon scientific men, which are worthy of note because more rare and costly than such distinctions usually are. At New Haven, on the day before commencement, a bronze statue of Prof. Silliman, for more than fifty years a teacher of chemistry, mineralogy, and geology in Yale College, and the founder of the *American Journal of Science and Arts*, was placed on its pedestal near the new chapel. The other honour is that of a medal struck at the U.S. Mint in Philadelphia, at the request of the colleagues and friends of Prof. Sylvester, to commemorate his residence in Baltimore during a period of seven years, marked, among other things, by the establishment of the *American Journal of Mathematics*. The medal, in size and general aspect, is not unlike that which was struck in commemoration of the life of Agassiz. On one side is an accurate and spirited portrait of the mathematician, with the name Sylvester; on the reverse a Latin inscription commemorates the fact that he was for seven years Professor of Mathematics in the Johns Hopkins University—from 1876 to 1883. The original medal in gold was sent to Prof. Sylvester, in his new home in the University of Oxford; a duplicate in silver was retained in Baltimore, and a few impressions in bronze have been distributed among his scientific friends and correspondents.

Science, in referring to the recent researches of Koch, states that work of value upon the subject of micro-organisms is not done in this country (the United States), nor will it be until some such encouragement is offered to investigators as is the case in France and Germany. This kind of research requires the rare combination of many forms of training, added to a critical, analytical, and judicial mind. These we can have; but until the facilities for the work are offered, until the necessity for personal sacrifice and self-denial is done away with, we can hope for no better work in the future than has been done in the past; in other words, what is first needed in order to place our own investigations upon an equality with those of the two countries mentioned above, is a thoroughly-equipped, fully-endowed laboratory, with a strong corps of well-trained and salaried officials. These remarks might very well have been written concerning our own country, and the official mission of Dr. Klein to India is a tardy recognition by our Government of the necessity of State intervention if scientific research is to be pursued with any hope of speedy and substantial practical results. The true way to encourage such inquiries (*Science* truly says) lies in the establishment of a Commission composed of men thoroughly trained and qualified for the work, and then to treat it as the German Government has treated its Cholera Commission, that is, to give it full powers and funds to allow the prosecution of its labours to the end.

THE death is announced at the age of seventy-five years of Sir Erasmus Wilson, the eminent surgeon.

THE death is also announced of Mr. John Aitken, J.P., of Urmston, well known as a geologist in the northern counties. Deceased was born in 1820. He was early distinguished for his application to scientific matters, and he twice filled the office of President of the Manchester Geological Society. He wrote for the Society's papers a number of articles relating chiefly to the geology of Clitheroe, Bacup, and Holcombe, and he also contributed to the *Geological Magazine* and the *American Journal of Science*. He furnished for Newbiggin's "History of the Forest of Rossendale" the geological section relating to that district.

SIR JOHN LUBBOCK has been compelled, for personal reasons, to abandon his intention of attending the meeting of the British Association at Montreal.

A COMMITTEE was appointed in 1882 at the Montreal meeting of the American Association for the Advancement of Science, "to confer with committees of foreign associations for the advancement of science with reference to an international convention of scientific associations." The committee consists of Dr. T. Sterry Hunt, Mr. Alexander Agassiz, and Prof. Simon Newcomb. If the British Association responds, as has been suggested, by also appointing a committee, the official channels for the interchange of opinion between the two national bodies will be suitably established on both sides. We (*Science*) are unable to make any authorised statement as to what the American committee has done or proposes, but its membership justifies the conviction that it is capable of efficient action, wisely planned. We shall await their report with interest.

THE Committee appointed by the Government at M. Pasteur's request to verify his experiments in the treatment of hydrophobia has just presented its first report. M. Bouley is president, his colleagues being MM. Beclard, Paul Bert, Tisserand, Villemin, and Vulpian. The Committee states that M. Pasteur's experiments have been entirely borne out. Inoculation with the attenuated virus of hydrophobia gives a dog immunity from the disease, just as similar treatment preserves a sheep from *charbon*. All the twenty-three dogs submitted by M. Pasteur as having been thus inoculated have resisted the strongest virus on inoculation, whereas the majority of the nineteen non-inoculated dogs have suc-

cumbed. Of the latter, six were bitten by mad dogs, three of them becoming mad, eight were subjected to intra-venous inoculation, all becoming mad, and five to inoculation by trepanning, all becoming mad. The result is decisive; but the Committee will now inoculate a large number of fresh dogs, and will compare these with an equal number of dogs not inoculated. It will likewise investigate the question whether after a dog has been bitten inoculation with the attenuated virus will prevent any consequences from the bite. M. Pasteur will lay before the International Health Congress at Copenhagen results which, as the Committee remarks, "are so honourable for French science, and give it a fresh claim on the gratitude of mankind."

A CORRESPONDENT living about two hundred yards from the river at West Chelsea complains that mosquitos first appeared sparingly in the middle of July, but are now almost nightly visitors. There is too much reason to fear, he states, that they are thoroughly acclimatised in this part.—Mosquitos and gnats are synonymous terms. Whenever the heat is greater than usual we constantly receive notices similar to the above. Possibly it renders the gnats more vicious, and at the same time the object of their attacks more irritable. Gnats (mosquitos) inhabit water (not sea-water) in their early stages, and from this reason it is practically impossible to import them, unless intentionally. The conditions at West Chelsea at the present moment are particularly favourable to the welfare of gnats (see article "Mosquito" in the new edition of the "Encyclopædia Britannica").

THE eighth International Medical Congress, of which the King of Denmark has consented to be the patron, was opened on Sunday in the Grand Hall of National Industry, Copenhagen, in the presence of the King and Queen of Denmark, the King and Queen of the Hellenes, the Crown Prince and Crown Princess of Denmark, and the rest of the Royal Family, the Danish Ministers, the Corps Diplomatique, the official authorities, civil and military, and delegates from Great Britain and Ireland, Germany, France, Russia, Austria, Holland, Belgium, Greece, Switzerland, Japan, New York, Columbia, Kentucky, and California. Addresses were delivered by the President, Prof. Panum, the Secretary, Dr. Lange, Sir James Paget, Prof. Virchow, and Prof. Pasteur. The assembly consisted of about 1500 members.

EARTHQUAKES have been frequent and widespread during the past few days. The inhabitants of the towns and villages along the whole range of the Alban hills were alarmed at two a.m. on August 7 by a sharp shock of earthquake, followed by another at a quarter past three. The direction taken by the wave was through Velletri, Nemi, Ariccia, Albano, Castel Gandolfo, and Rocca di Papa and Frascati. The shocks were most severely felt at Rocca di Papa, but no damage was done beyond the felling of two chimneys at Ariccia. At half-past three a severe shock, quickly followed by another, was distinctly felt at Rome, and that which shook the Alban hills extended also as far as Porto d'Anzio, on the coast.

AN earthquake shock shook the most solid buildings in New York at two o'clock on Sunday afternoon, and produced a sensation like that on board a steamer under way. At Brooklyn the residents were frightened into running out of their houses. The earthquake suddenly moved along the Alleghany Mountains and their eastern slopes, from Virginia to Vermont, in a direction from south-west towards north-east, extending over the entire country from the mountains to the ocean. The most southerly city in which the shocks were noticed was Washington, and the most northerly Brattleborough, Vermont. Two distinct shocks, each of about two seconds' duration, with an interval of about four seconds, were generally felt, while in New York and further eastwards a slight third shock was experienced a few minutes afterwards. The earthquake was observed at nine minutes past two o'clock in the afternoon at Philadelphia, and somewhat later to the eastward of this city. It was most severe in New York City, Connecticut, and Boston. The vibration was slighter elsewhere.

SLIGHT earthquake shocks, recurring at short intervals, have recently been felt at Massowah.

PROF. MILNE, of Tokio, Japan, writing to the *Times* on the subject of the Essex earthquake, concludes as follows:—"Before earth movements can be generally understood, it is necessary that they should be observed as other natural phenomena are observed. A reason that has been expressed against the establishment of seismometers in British observatories is that in Britain earthquakes are a rare occurrence. Such a reason appears to arise from an imperfect acquaintance with the phenomena to be observed. Earth-tremors, which are minute earthquakes, may be observed in Britain every day. Messrs. George and Horace Darwin have shown that such movements are of common occurrence in Cambridge. Then there are the slow earthquakes or earth-pulsations, like those which I have from time to time observed in Tokio. Whether these exist in Britain cannot be known until they are sought for. That they existed on the outer rim of the area where the Essex earthquake was felt is tolerably certain. It is also certain that shortly after great earthquakes—as, for instance, some which have shaken South America—pulse-like motions have been observed in the bubbles of astronomical levels at places as distant as St. Petersburg. When we consider that we are observing meteorological changes with which earth-tremors have a close relationship, that we observe the tides, magnetic and electric changes in our earth, and the escape of gas in our mines, with all of which earth-movements may be closely associated, when we possess so many earthquake-shaken colonies, and send our Navy and mercantile marine to all the earthquake countries of the world, it would certainly not be an unreasonable undertaking for us to investigate the ill-understood phenomena which continually occur beneath our feet. We study our oceans, our atmosphere, the sky above us, and, I may add, the ice at our poles, while the changes in the earth on which we live are almost neglected."

MESSRS. COTTEAU AND KORTHALS, members of the French Mission sent by the Minister of Public Instruction to explore the Krakatoa volcano, write from Batavia on June 2 that the object of the expedition has been fully realised. Soon after their arrival at Batavia on May 14, the Dutch Colonial Government placed at their disposal a small steamer, on board of which they started for the Sunda Strait on the 21st. Along the west coast a well-marked line, running at an elevation of from fifty to eighty feet above sea-level, indicated the limit reached by the terrible wave that spread disaster far and wide towards the end of August 1883. The plantations had been swept away, and all the houses of this populous district, together with the town of Anjer, had completely disappeared. On the 23rd the steamer cast anchor at the head of Lampong Bay on the south coast of Sumatra, whence a visit was paid to the Telok-Betong district. Here the extensive and thickly-settled coastlands had assumed the aspect of a desolate swamp, relieved here and there by a few bamboo huts recently set up. Nearly three miles inland lay the steamer *Borouw*, which had been borne on the crest of the wave into the forest, where it now forms a sort of bridge across a small stream. On the 25th the formerly fertile and densely-peopled islands of Sibuku and Sibesi were successively visited and found to be entirely covered by a deposit of dry mud several yards thick and furrowed by deep crevasses. Of the inhabitants, all had perished to a man. Continuing the trip on the 26th to Krakatoa itself, the mission was surprised to note the complete disappearance of the three islands of Steers, Calmeyer, and the islet east of Verlaten, which had risen above the

surface at the time of the eruption, but which are now covered by 12 or 14 feet of water. Approached from the north Krakatoa seemed wrapped in a whitish smoke, vapours apparently issuing from fissures on this side, and settling on the summit, which is at present 2730 feet high. It was at this point that the great convulsion took place on August 26-27, when about half the island was blown into the air. A closer examination showed that what had been taken for fissures were simply ravines, and the vapours were clouds of dust stirred up by stones incessantly rolling down the steep slope of the mountain. This was accompanied by a continuous noise like the rattling of distant musketry, while stones of a certain size were seen whirling in the air, then falling and ricochetting down to the sea. Notwithstanding the evident danger, the boats of the expedition succeeded in approaching the foot of the volcano and collecting specimens of the rocks at several points. The same afternoon they reached the island of Verlaten, formerly one mass of verdure, now uniformly covered with a layer of solidified ashes about 100 feet thick. The deep crevasses, widened by the erosion of tropical rains, give the aspect of a glacier to this island, which has been doubled in extent by the deposits from the last eruption. Returning next day to Krakatoa the members of the expedition found a safe landing place, where it was possible to study the nature of the rocks and other matter ejected by the volcano. No trace was found of animal or vegetable life, with the exception of a solitary little spider, and the solidified bed of mud and ashes was estimated in some places to have attained a thickness of from 200 to 260 feet. A black rock rising a few yards above the surface about a mile and a quarter from the present shore, represents a last fragment of the portion of the island engulfed during the eruption. After touching at Lang Island, which presented much the same appearance as its neighbour Verlaten, the expedition concluded its survey of the Strait, landing on the 28th at Merak at the north-west extremity of Java. Merak had shared the fate of Anjer, and the coast-line in this district had been considerably modified. The expedition returned to Batavia on the 29th, after determining two new facts—the disappearance of the islands upheaving during the eruption, and the total cessation for the present of all volcanic activity at Krakatoa.

On Saturday, August 9, M. Renard, Captain of Engineers, and M. Krebs, Captain of Infantry, made an experiment with the directing balloon which they are constructing at the expense of the French Government in the aëronautical works of Chalet Meudon. The balloon, which is about 60 metres in length and 10 metres in diameter, carries a long platform of about 40 metres in length and 3 metres in breadth. At one of its extremities sit the aëronauts in a car. The aerial helix and a gramme magneto-electric machine are placed at the other. The voltaic elements and ballast are disposed on the platform. The wind not being strong, the aëronauts ascended and tried first the effect of their rudder, which is a sail of about 10 metres square. The results were very satisfactory indeed, and the steering of the balloon remarkably quick and easy. The balloon was drifted by the wind from Chalet Meudon to Petit Bicetre, above the Meudon woods. Then the aëronauts, wishing to return home, adjusted the rudder and the experiment succeeded wonderfully; in five minutes the distance, which is about two miles, was run. The balloon landed just before the doorway of its wooden house. This experiment will be tried again in a few days for a longer distance. The system practised by the French officers is a slight modification of the one used by Gaston Tissandier and described in Nature. The French officers were originally adherents of the helix moving round an axis traversing the balloon, but the result of the experiments published by Tissandier seems to have modified their opinion.

M. F. Lhoste, Secretary of the Académie d'Aérostation Météorologique de France, who started in a balloon from Boulogne on Thursday last, descended at Romney, fifteen miles from Folkestone, at half-past eight o'clock the same evening. M. Lhoste left Boulogne at seven p.m. He encountered three distinct currents of air, one of which carried him in the direction of the North Sea. The descent was effected without difficulty.

Already a prospectus has been issued of the International Exhibition of Inventions and of Musical Instruments, to be opened in May 1885, in the buildings now standing in the gardens of the Royal Horticultural Society at South Kensington. The Exhibition will have all the advantages of royal patronage and support. Her Majesty the Queen becomes patron, and the Prince of Wales assumes once more the duties of president. The Executive Council, appointed by the royal president, having for chairman Sir Frederick Bramwell, F.R.S., vice-president of the Institute of Civil Engineers, and for vice-chairman the Marquis of Hamilton, is composed of Sir Frederick Abel, C.B., Mr. I. Lowthian Bell, F.R.S., president of the Institution of Mechanical Engineers, Mr. Birkbeck, M.P. (honorary treasurer), Colonel Sir Francis Bolton, Sir Philip Cunliffe-Owen, C.B., C.I.E., Prof. Dewar, F.R.S., Mr. Joseph Dickenson, Sir George Grove, D.C.L., Mr. E. W. Hamilton, Mr. Henry E. Jones, M.Inst.C.E., Mr. W. H. Preece, F.R.S., Sir E. J. Reed, M.P., F.R.S., Prof. Chandler Roberts, F.R.S., Mr. John Robinson, Mr. Warington W. Smyth, F.R.S., Dr. Stainer, and Mr. R. E. Webster, Q.C., with Mr. Edward Cunliffe-Owen as secretary. Mr. J. R. Somers Vine will be the City and official agent. The idea upon which the Exhibition is planned is not to bring together a mere collection of models of inventions, but rather to illustrate the progress which has been made in the practical applications of science during the past twenty years. In order to carry out this intention the Council will, as far as possible, confine the exhibits to processes and appliances, products being admitted only where they are themselves novel or where their introduction is required to make the purpose or advantages of that which is new in any process more interesting and intelligible. It is not proposed to allot space for manufactured goods unaccompanied by any illustrations of the process of manufacture. Generally it may be said that, as far as is practicable, inventions will be shown by models, with, in the case of models of entire machines, actual specimens of the portions improved under the exhibitor's patent, and when the invention relates to parts only the whole machine will not be admitted unless indeed the improvement effected cannot be sufficiently shown without the exhibition of the entire apparatus. The limitations of space which make these restrictions necessary, also compel the Council to decline, unless in exceptional circumstances, to receive objects which have already been shown in the Smoke Abatement Exhibition, 1881, in the Fisheries Exhibition, 1883, or in the present Health and Education Exhibition, and it is thought that the annual shows of the Royal Agricultural and kindred Societies have served so well to exhibit inventions bearing upon agriculture that it will suffice to present a few typical examples (and these models or diagrams) of each class of improvements effected during recent years.

The U.S. National Academy of Sciences recently received a gift of 8000 dollars from the widow of the late Dr. J. Lawrence Smith. The deed of trust has now been executed, and provides that the interest of the fund shall be used in striking a gold medal of the value of 200 dollars, to be called the "Lawrence Smith Medal," and to be awarded by the Academy, not oftener than once in two years, "to any person in the United States of America, or elsewhere, who shall make an original investigation of meteoric bodies, the results of which shall be made known to the public, such result being, in the opinion of the National Academy of Sciences, of sufficient importance and benefit to science to merit such recognition."

Any sums which may accumulate from the interest of the fund, above what is required for the purposes specified, are to be used "in aid of investigation of meteoric bodies, to be made and carried on by a citizen or citizens of the United States of America."

THERE being a notable difference between the determinations of specific weight of the normal hydrate of sulphuric acid, H_2SO_4, which have been made by Marignac in 1853 and 1870, and later on by MM. Schertel, Kohlrausch, Lunge, and Naeff, Prof. Mendeléeff, aided by M. Pavloff, has recently determined it again with all possible accuracy, and communicated the results of his determinations to the Russian Chemical Society (*Journal*, vol. xvi. fasc. 5). The hydrate was crystallised four times, the operations being made in a perfectly dry atmosphere of carbonic acid. Out of 6 kilogrammes, a remainder of only 300 grammes was received. The thus prepared hydrate melted at 10°·1 to 10°·6, and an accurate titration of it gave the following figures: 81·71, 81·52, and 81·58, that is, on the average, 81·6 per cent. of SO_3, the theoretic percentage deduced from the chemical formula being 81·64. The specific weight of the hydrate has been determined with great accuracy, and the average result, with all necessary corrections, was 1·83295 at 19°·02. The reduction to 15°, as compared with water at 4°, being made with Marignac's data for dilatation, the final result will be 1·8371, which figure differs only by 0·0001 from that of Marignac, and widely differs from those of Kohlrausch, Lunge, and Naeff.

WHEN submitting the Baku naphtha to fractional distillation, carried on at each 2°, Prof. Mendeléeff had shown that the specific weight of the products of distillation, while rising on the whole together with temperature, decreases however three times, namely, between 55° and 62°, between 80° and 90°, and between 105° and 110°. He shows now, in a recent communication to the Russian Chemical Society (*Journal*, vol. xvi. fasc. 5), that this is not a peculiar feature of the Baku naphtha, but that the same decrease of specific weights is displayed also by American naphtha, if this last be submitted to fractional distillation at each 2°, and that the phenomenon is produced at nearly the same temperatures. The products that boil below 60° were insufficiently represented in Prof. Mendeléeff's samples; but from 60° (where the specific weight, reduced to 17°, like all following, was 0·6642) until 124° (where it was 0·7322), there are two decreases of specific weight. Thus, at 80° it was 0·7347, but only 0·7069 at 92°, that is, the same as at 75°. After that it increases until 104°, where it reaches 0·7543; but it soon decreases for a second time, and at 115° to 117° it reaches 0·7270, that is, the same figure as it had between 85° and 98°. Beyond 117° it continues to rise. Both kinds of naphtha—Caucasian and American—however different their origin, thus display the same phenomena at nearly the same temperatures; the corresponding specific weights, however, are not the same; the portion at 80° has, in the Baku naphtha, a specific weight of 0·7486, and only 0·7347 in the American; and at 100° the respective densities are 0·7607 and 0·7380. The amounts of substance distilled at each temperature are also different. The researches will be continued in Prof. Mendeléeff's laboratory.

WE have been requested to state that at the meeting of the Essex Field Club, referred to in last week's NATURE (p. 343), the natural history and archæological conductor who addressed the Club on the "salting mounds" and other subjects was Mr. Henry Laver, F.L.S., of Colchester.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. T. S. T. Tregellas; a Striped Hyæna (*Hyæna striata*) from North Africa, presented by Sir John H. Drummond Hay, K.C.B., C.M.Z.S.; three Greater Sulphur-crested Cockatoos (*Cacatua galerita*), three Leadbeater's Cockatoos (*Cacatua leadbeateri*), a White-backed Piping Crow (*Gymnorhina leuconota*) from Australia, a Red-sided Eclectus (*Eclectus pectoralis*) from New Guinea, a Blue and Yellow Macaw (*Ara ararauna*) from South America, six Amherst Pheasants (*Thaumalea amherstiæ*) from China, eight Himalayan Monauls (*Lophophorus impeyanus*) from the Himalayas, two Javan Peafowls (*Pavo spicifer* ♂ ♂) from Java, presented by Mr. Charles Clifton, F.Z.S.; a Rough-legged Buzzard (*Archibuteo lagopus*), British, presented by Sir R. Payne Gallwey, Bart.; a Cockateel (*Calopsitta novæ-hollandiæ*), a Rose-Hill Parrakeet (*Platycercus eximius*) from Australia, presented by Mr. J. W. Dixon; a Green Turtle (*Chelone viridis*) from the West Indies, presented by Mr. A. E. Painter, F.Z.S.; a Loggerhead Turtle (*Thalassochelys caouana*) from the Atlantic Ocean, presented by the Surrey Commercial Docks Company; a Leopard Tortoise (*Testudo pardalis*) from South Africa, presented by Mr. William Lane; a Slow-worm (*Anguis fragilis*) from Norfolk, presented by Mr. T. E. Gunn; a Bonnet Monkey (*Macacus sinicus*) from India, a Blue-fronted Amazon (*Chrysotis æstiva*) from Brazil, a Grey Parrot (*Psittacus erithacus*) from West Africa, an Alligator Terrapin (*Chelydra serpentina*) from North America, deposited; two Jardine's Parrots (*Pæocephalus gulielmi*) from West Africa, two —— Conures (*Conurus perlatus*) from the Lower Amazons, an Electric Eel (*Gymnotus electricus*) from British Guiana, purchased; a Mule Deer (*Cariacus macrotis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE NEXT MINIMUM OF MIRA CETI.—In the ephemeris of variable stars for 1884 in the *Vierteljahrsschrift*, the next minimum of Mira is fixed to 1884 October 24, a date which does not appear to result from Argelander's formula of sines, as it is given in Schönfeld's Catalogue of 1875, viz.:—

$$\text{Epoch Min.} = 1866 \text{ August } 8{\cdot}0 + \overset{\text{d.}}{331{\cdot}3363} \,.\, E$$
$$+ \overset{\text{d.}}{10{\cdot}48} \sin\left(\frac{360^\circ}{11} \,.\, E + \overset{\circ}{282} \; \overset{\prime}{45}\right)$$
$$+ 18{\cdot}16 \sin\left(\frac{45^\circ}{11} \,.\, E + 31 \; 15\right)$$
$$+ 33{\cdot}90 \sin\left(\frac{45^\circ}{22} \,.\, E + 70 \; 5\right)$$
$$+ 65{\cdot}31 \sin\left(\frac{15^\circ}{11} \,.\, E + 179 \; 48\right)$$

For the present year E = 20, and hence substituting logarithms the four perturbations become—

$$+ [1{\cdot}02036] \sin (\overset{\circ}{217}{\cdot}29) = - \overset{\text{d.}}{6{\cdot}35}$$
$$+ [1{\cdot}25912] \sin (113{\cdot}07) = + 16{\cdot}71$$
$$+ [1{\cdot}53020] \sin (110{\cdot}00) = + 31{\cdot}65$$
$$+ [1{\cdot}81498] \sin (207{\cdot}07) = - 29{\cdot}72$$

The Julian date of the initial minimum is 2402822, and we have—

	2402822·0
331·3363 . E	6626·73
Sum of perturbations	+ 12·29
Julian date of next minimum	2409461·0

Which it will be seen from the *Nautical Almanac* (p. 486) corresponds to 1884 October 11. In 1882 by a very precise determination of the time of minimum, Schmidt found that it occurred on December 16, which is 18 days earlier than the date given by Argelander's formula, and the previous maximum had also been earlier by about 19 days. If this correction still applies the next minimum might be expected to fall about September 23, or a month earlier than the *Vierteljahrsschrift* has it. Still there is the possibility that Prof. Schönfeld may have applied corrections to the formula.

The present year's minimum may be therefore advantageously observed. In that phase Mira descends to about the brightness of the well-known star following it, not far from the parallel, or to about 8·5 m.

Another of the more interesting variables, χ Cygni, may be expected at a maximum about November 15, and R Leporis, "the crimson star," at a minimum on January 5.

THE DOUBLE-STAR 99 HERCULIS.—Mr. S. W. Burnham, in his last Catalogue of double-star measures, refers to a statement by M. Flammarion to the effect that the change in the position of the companion of 99 Herculis (one of Alvan Clark's discoveries) very nearly corresponds to the proper motion of the large star. But although the alteration in position between Dawes' measures in 1859 and Mr. Burnham's in 1880, may be fairly represented by rectilinear motion, it will hardly appear, when the best value we can assign at present for the proper motion of 99 Herculis is introduced, that it accounts for the observed change in the position of the companion. If we compare Bradley for 1755 with the Greenwich Catalogue for 1864, employing the accurate formulæ, we find :—

Secular proper motion in right ascension ... $-\ 11''\cdot34$
,, ,, ,, declination ... $+\ 6''\cdot90$

Mädler assigned for the respective proper motions $-\ 10''\cdot4$, and $+\ 7''\cdot0$.

Taking for comparison the following measures of 99 Herculis,

	Position	Distance	
1859·63 ..	$347^\circ\cdot2$ ...	$1''\cdot705$ ..	Dawes
1880·18 ...	29·9 ...	0·91 ...	Burnham

we find on bringing up Dawes' measures to Burnham's epoch, with the proper motions of the principal star given above, the angle of position becomes $81^\circ\cdot5$, and the distance $1''\cdot65$, showing a great difference from the result of the American astronomer. It seems at least probable, as he remarks, that it will prove to be a physical pair.

THE WATER SUPPLY CONFERENCE

THE Water Supply Conference of the Society of Arts, held at the National Health Exhibition, in the unavoidable absence of the President, H.R.H. the Prince of Wales, was opened by Sir Frederick Abel, C.B., F.R.S., chairman of the Council, who alluded in his introductory address, to these Congresses having been originated by His Royal Highness, who hoped a comprehensive scheme might be elaborated that would provide not only for the urban populations, but for the rural communities. He alluded to the good and useful work done by the Congress held in 1878, and in 1879, and reviewed the present position of the water-question in this country.

The papers read at the Conference were placed under three heads, viz. :—"*sources of supply*," "*quality of water*, with methods of filtration and softening," and "methods of *distribution*, with modes of giving pressure, house fittings, discovery and prevention of waste." Under all heads valuable papers were contributed, and the Society may again be congratulated on bringing together a jury of experts capable not only of showing us the weak points in our existing water-supply, but the methods by which these defects may be remedied. This was done to a large extent by the previous Conference, but the dangers then pointed out have been hardly appreciated, owing to the years of the Conference being followed by a remarkable succession of wet seasons. Now that a hot summer is succeeding a dry winter, the gravity of the situation is forcing itself upon public attention, and the importance of husbanding our water resources is found to be a matter of vital necessity, the neglecting of which has already facilitated the spread of English cholera, in certain districts, and will be a constant element of danger, should Asiatic cholera appear on this side of the English Channel.

Rainfall being the source of all water supply, it may be well to first notice the paper contributed by Mr. G. T. Symons, F.R.S., who, just a quarter of a century ago, instituted the first general series of rainfall observations ever made in this country, and who since that time has been gradually increasing their number, until there are now nearly 3000 observers, no less than 2433 stations having furnished perfect records of rainfall last year. Worthy of all praise as is this remarkable voluntary staff of observers, not only giving their services, but actually contributing 99 per cent. of the cost of publishing the observations made, it is obvious, looking to the direct bearing such observations have on engineering, agricultural, and sanitary questions, bearing on the health and welfare of our population, that the scope of the inquiry should be enlarged so as to increase its sphere of usefulness, and that it should be placed under a Government department with a grant from Parliament, and the inquiry be no longer crippled for want of funds as regards possible and necessary extensions, though ten years ago the British Association for the Advancement of Science, feeling it their duty to initiate, rather than support, investigations of national importance, withdrew the vote with which they had aided the work for many years, it is due to Mr. Symons to point out that he has not merely maintained the standard of excellence found in his annual volumes of that period, but has increased their size and usefulness. In his paper Mr. Symons urges as a question of general policy the necessity of the formation of an hydraulic office, the early duty of a Government being "to see that all parts are completely supplied with the chief necessary of life. Englishmen," he says, "have a dread of centralisation, but in many ways they pay a long price for their dread. At present, it is not often that any town can even state before Parliament its views as to the effect upon it of what its next neighbour may be obtaining powers to do," and which, when passed by Parliamentary Committees become law, and "law for all time to come;" he truly adds that "no one can foresee what will be the total population of the country a century hence. No one can tell where the bulk of the people will reside, nor what will be the need for water in various parts of the country," and he justly urges that special water rights, "now asked to be created, should be subject to revision, *without compensation*, after the lapse of 100 years."

Mr. E. Bailey-Denton, in his paper on "The Water Supply of Villages and Rural Districts," points out that though a state department exists charged with sanitary matters, the condition of our rural districts as regards water supply "is a positive disgrace," and he considers the department should have their efforts specially directed to the protection of small communities, and states that those who form the "Local Boards" and "Boards of Guardians," having jurisdiction over such districts are elected under pledges to oppose all sanitary works that will increase the rates, and that even when men of knowledge and position are elected to such posts—outvoted by the majority they fall back to quietly agreeing with the *laissez faire* policy of their colleagues, and allow their constituents to continue to inhale and imbibe those germs of disease which float in the foul air that surrounds them, and are present in the only water provided for their use. Mr. Denton is evidently of the opinion that the writer has already advocated in these columns, that the Local Government Board should not only have the power to sanction local authorities providing pure water and efficient sanitary arrangements, but should themselves survey the country and seek out the districts where advantage is not taken of the law, as it even now exists, and to compel the authorities to remedy the abuses and shortcomings discovered.

In the present position of our knowledge it would be difficult, and often impossible, for an engineer to advise such a rural authority, suddenly called on to provide itself with an efficient water supply, even were the legal difficulties, and cost of parliamentary struggles obliterated. Thanks to Mr. Symons, we know something of the rainfall, but as Mr. Conder and others have pointed out, our knowledge of the discharge of our rivers is lamentably small. Daily gaugings have been taken of the Thames, but no systematic examination of the quantities run off by streams draining equal areas of rocks of varying degrees of permeability have been carried out, and the necessity of such observations being taken in all our streams cannot be too highly insisted on, and should be made a matter of State care. The few observations we have were chiefly made in the last century by Rennie, if we except the comparison of chalk and clay basins, made by Mr. C. Homersham, who showed the large quantity of water absorbed by the chalk, which never appears as streams. As regards underground waters, our knowledge is also not yet sufficiently definite to safely predicate the quantity of water a given unknown district will yield. A large body of information has been published by the Underground Water Committee of the British Association, during the past ten years, from which the direct relation of yield to rainfall, modified by degree of permeability is clearly made out, and details given of actual supplies obtained in enormous quantities, in certain districts, but what is still required, is a systematic examination of the height of water in wells and borings throughout the kingdom, and until the seasonal variation is clearly established, the minimum yield to be obtained in a given district, during a dry year, and still more after a succession of dry years cannot be ascertained, or calculations made be depended on with any safety. Information of this class is being steadily

accumulated in the Epsom, Croydon, and in some other districts by Mr. Baldwin Latham, C.E., who is ascertaining the seasonal variation in level of the underground waters, and the difference of cubic discharge of springs by self-recording apparatus. Valuable as are such observations for special districts for general use and public advantage, it is necessary that they should be extended to the whole country and be made by official observers for public use, and free access to the results.

In a paper on "Water from the Chalk," Mr. Joseph Lucas alluded to the work he has been doing during the past twelve years in measuring the height of the water in the wells over a large district in the Thames and Hampshire Basins, connecting together the points of observations by imaginary lines, or underground contours. He is able to map out with some degree of accuracy the height at which water stands in the rocks, the varying width, or proximity of the contours, indicating the varying decrease or increase of the steepness of the water gradients, *i.e.* the angle which the slope of the water-plane makes with the sea-level, which, as shown by the Rev. J. Clutterbuck in 1841, varies in the chalk from 14 to 47 feet per mile. Mr. Lucas is of opinion that a comprehensive and uniform survey of the sources of water-supply, both surface and subterranean, should be carried out by the nation, and that maps should be constructed, "defining levels, areas, and quantities of water."

The Geological Survey have done much to prepare the way for such an examination as was pointed out by Mr. Edwin Chadwick, C.B. at a previous Congress, and it is encouraging to note that the first four papers read on "Sources of Supply" at the present Conference, were contributed by three present officers, and one former officer of that staff. Mr. Whitaker's paper commenced by pointing out that ordinary geological map, including the greater number as yet issued by the Geological Survey, are of little use in estimating the quantity of water obtainable from a given porous rock that may be represented on the map, and whose water-bearing capacity may be well known, owing to the thick covering of various beds of clay, sand, gravel, loam, and alluvial silt, together called by geologists drift, which obscures the solid geology, and where the beds consist of impermeable material entirely cut off the percolation of rainfall into the pervious rock beneath. Before, therefore, any estimate can be made with any degree of accuracy, of the quantity of water capable of being yielded by a given area of permeable rock, as represented on the ordinary geological map, it is necessary to have a Drift survey, showing the actual condition of the surface. Such maps are now being issued by the Geological Survey, the various rocks, being shown by their proper colour, in the areas, when they are not overlaid by any material, the surrounding districts being coloured to indicate the nature and character of the drift deposits overlying them, distinguishing the different clays and various gravels by distinct tints. For waterworks purposes, so elaborate a classification is not requisite, and in the interesting and valuable series of maps Mr. Whitaker laid before the Congress, the results of many years of work, he has adopted the following classification:—1, bare chalk; 2, chalk covered only by beds of a permeable kind; 3, chalk protected by beds of mixed or varying character; 4, chalk protected by impermeable beds. The result of Mr. Whitaker's investigations is to curtail the somewhat excessive estimates that may have been made in bygone years of the amount of chalk area available for the absorption of rain, but he states that the "chalk remains our chief water-bearing bed in the south-east of England; for though not always coming up to some of the sand-beds in permeability or porosity, it is pre-eminent over all other geological formations in thickness and extent of outcrop."

Mr. Topley contributed an interesting paper on a subject he has already done good and original work, "Water Supply in its Influence on the Distribution of the Population." He shows there "is a well marked and constant relation between the outcrop of porous strata and the parish or township boundaries, the longer axes of the parishes crossing the outcrops more or less at right angles." The arrangement of parish boundaries depends upon the sites of early settlements, which were entirely controlled by the outcrop of the water-bearing beds. Mr. Topley points out that with the river, London has at present no less than four different sources of supply of water, each giving a different quality, and he notes that no city in Europe is better situated for supplying itself from its own area, but it has become so vast that all sources have become insufficient. He notes that most of the other great capitals of Europe are also situated on basins capable of yielding deep well water, and instances Paris, Berlin, and Vienna.

Mr. De Rance, in a paper on "A Possible Increase of Underground Water Supply," endeavoured to show that the flow of intermittent springs might be increased, and the violence of floods diminished by the construction of "dumb wells," through impermeable beds to pervious beds below, draining what is now unproductive rainfall, passing in destructive floods to the sea, into permeable rocks which are now not storing water owing to their being covered by impermeable formations.

Mr. Edward Easton gives a useful *résumé*, gathered from his own practical experience, of well recognised principles which should govern the supply of water for domestic and other purposes, which, he justly observes, are too often neglected or forgotten. He appears to have a very decided predilection for soft water in preference to hard, and alludes to the value and cheapness of the lime-softening process of Prof. Clark; as regards filtration of supplies, in which it is found impossible to altogether prevent the chance of contamination, the filtering medium should include some deodorising agent, and he refers to the good results obtained in this direction at Wakefield by Spencer's magnetic carbide of iron, and at Antwerp by Prof. Bischof's spongy iron; in both cases the water was much contaminated, and was rendered perfectly wholesome. Referring to the dangerous practice of storing water in cisterns, he states that after an elaborate and exhaustive examination of the waters supplied by the London water companies, by Sir Frederick Abel, assisted by Dr. Dupré, Mr. G. H. Ogston, Prof. Voelcker, and the late able chemist to the Metropolitan Board, Mr. Keates, it was found that during the session of 1877-8, when two bills were introduced into Parliament at the instance of the Metropolitan Board of Works for purchasing the undertakings of the London water companies, and for providing a separate supply from the chalk for drinking purposes, that whilst the water in the main was in almost all cases excellent, the condition and position of the cisterns frequently rendered it utterly unfit for human consumption, a condition of affairs affording a most fruitful source of disease, and not alone confined to the dwellings of the poor, cisterns fixed on the roofs of the better class of houses being "rarely sufficiently covered, and often open to contamination from soot, dust, inroads of blackbeetles, and other abominations." Mr. Easton quotes Sir F. Bolton as to the importance of waste-pipes from cisterns being carried outside each house and the end left exposed to the air, instead of communicating, as now, with the drains, from which gases flow back into the cisterns, and are absorbed by the water; but it is to be hoped, with the steadily increasing expansion of the constant service in London, this frightful evil will cease to exist. According to Colonel Sir F. Bolton's return for the month of May, the quantity of water supplied to London amounts to 32 gallons per head per day, about 20 per cent. of which, say 6 gallons, it is estimated is used for other than domestic purposes, leaving 26 gallons per head as the quantity supposed to be absolutely consumed in the houses, while long practical experience has proved that the water really required is not half that quantity, and there can be little doubt that a system of supervision like that carried out at Liverpool would have similar results. The use of Deacon's meter has reduced the consumption of water from 33 to 22 gallons per head per day; this ingenious instrument enables waste of water to be localised, and the house or place detected where the flow-off is taking place.

Mr. Easton then shows the advantage to consumer and supplier of a constant service being given to each house by water, the quantity being regulated by the rateable value of the property, but returns to the keynote of all the speakers, that "it is useless to discuss the method and conditions of supply if the sources of water are not to be preserved to us," and adds, "it is quite certain that with the immense growth of the population of this kingdom, it will not be long before this preservation becomes a pressing necessity."

Mr. Easton repeats the proposition he made in his Presidential address to the Mechanical Section of the British Association at Dublin in 1878, which, expressing as it does a widespread feeling shared by all who have given attention to the subject, it may be well to quote at length. Mr. Easton considers that the question "of the management of rivers is of sufficient importance to make it worthy of being dealt with by new laws, to be framed in its exclusive behalf;" and that "a new department should be created—one not only endowed with powers analogous to those of the Local Government Board, but charged with the duty of collecting and digesting for use all the facts and knowledge necessary for a due comprehension and satisfactory dealing with every river-basin or watershed area in the United Kingdom

—a department which should be presided over, if not by a Cabinet Minister, at all events by a member of the Government who can be appealed to in Parliament."

Mr. J. Mansergh, C.E., states that "altitude and geological structure of a district on the two principal factors which determine what the source of water-supply must be in each district." He divides source of supply into (*a*) aboveground, and (*b*) underground. The former he subdivides, into—1. Water taken from heads of streams by pipes, just when it ceases to be underground water, as in the case of Lancaster. 2. Water obtained from natural lakes, as in the case of Glasgow. 3. Water collected from high-lying moorland watershed areas, as at Manchester. 4. Water taken from a large river flowing past a town, as the Thames and Lea, near London. His second class (*b*) he does not subdivide, and includes all waters taken from all classes of stratification; he appears to take twelve degrees of hardness of Dr. Clark's scale as the maximum limit of safety for health, and regards a pure soft supply as preferable to a pure hard supply, using the word "pure" to mean absence from organic impurity. Speaking of towns which are compelled by position, and on the score of expense to be content with a water-supply derived from an adjacent river, he states that such sources "would be inadmissible but for the great rehabilitating process which nature silently carries on in a river, and to which chemists apply the term 'oxidation.'" In this wonderful process the polluting organic matters which the water contains are converted by the agency of oxygen into harmless inorganic salts, and the water again becomes fit for the use of man. He here refers to the burning controversy between the two schools of opinion on this matter, which have at their heads Dr. Frankland and Dr. Meymott Tidy respectively; the former admits that oxidation is effective in converting the most vile contamination into a harmless condition, but does not admit it destroys the organised germs, which he believes cause the virulent zymotic diseases, and which, being indestructible, may travel scores of miles in a running stream without being deprived of their fatal potency. Dr. Tidy, on the other hand, denies the existence of the germs, and affirms, after a run of a few miles, a river is fully oxygenated. Mr. Mansergh observes that, though Dr. Frankland's opponents appear to have the facts in their favour—as London, a city chiefly supplied from a polluted river, being one of the healthiest cities in the world—yet the "germ" theory is making steady advances under the investigations and researches of competent men.

Since the London water companies have come under the official supervision of Sir Francis Bolton, large sums of money have been spent in increasing the efficiency of the subsidence tanks, by greatly augmenting their capacity, in fact, their operations have converted them into storage reservoirs; from these the water is delivered into filter beds, the varieties in the construction of which, adopted by the different companies, are shown in the angle of the very interesting water pavilion erected in the Health Exhibition, under the auspices of Sir Francis Bolton, and which is full of interest to the student of the subject, and is decorated with some very artistic representations of the various waterworks on the banks of the Thames.

Any scheme of new legislation, and construction of a new department to carry out its provisions should, in the opinion of the writer, be made to include underground water supplies, the state of the law at the present time being exceedingly unsatisfactory, and the decisions of parliamentary committees being uncertain and contradictory. The law places underground water in the category of wild and free creatures, that he who can catch can hold, and just as one landowner can shoot a hare on his own property that has been bred on his neighbour's land, so can he take, by sinking a well, the water that has been received on his neighbour's property, notwithstanding his neighbour may be wholly dependent upon it for water supply, and it may have been used from time immemorial, and further than this, on the principle "of doing what you like with your own," he may actually pour poison down his own well, and destroy the value of the water in the well on his neighbour's land without hindrance and without compensation. Two of the essayists at the congress referred to the recent judgment of Justice Pearson confirming this view.

Considering the opinions expressed in the papers read at this congress, and the statements made in the discussion upon them, it appears to be generally believed by those who have made the water question a special study, that the existing complex legislation, sanctioning various and often antagonistic authorities in our water-basin, is productive of the greatest harm to the community, and can only be remedied by the constitution of an hydraulic department with absolute control over streams from their source to their outfall; that such department should at once make systematic arrangements for taking rain-gauge observations, the gauging of the whole of our streams, and the height and seasonal variation of the water stored in the rocks beneath the surface.

C. E. DE RANCE

THE CITY AND GUILDS OF LONDON INSTITUTE

FROM the Report on the Technological Examinations, 1884, we learn that a considerable increase is shown in the number of candidates at the recent examination, May 28, 1884, as compared with that of the previous year. In 1883, 2397 candidates were examined, of whom 1498 passed. In 1884, 3635 were examined, of whom 1829 passed. There is also shown a satisfactory increase in the number of centres at which the examinations have been held.

From the returns received at the office of the Institute in November last, it appears that 5874 persons were receiving instruction, with a view to these examinations, in the registered classes of the Institute. The number of students at the corresponding period of the previous year was 4052, this being 585 in excess of the number in 1882. Of the candidates who received instruction in the registered classes of the Institute, about one-half presented themselves for examination; of the remaining candidates who came up, some had received instruction in colleges the Professors in which do not accept payment on results, whilst others had supplemented their workshop practice by private study.

This year, as last year, Glasgow heads the list of centres from which the largest number of candidates have passed, the number being 139, as compared with 123 in 1883. Of the other centres, Manchester sent up 115 successful candidates, as against 76 in the previous year; Bolton 98, as against 117; Bradford 90, as against 51; Leeds 70, as against 64 (50 coming from the Yorkshire College, as against 43); Preston 59, as against 46.

In carpentry and joinery, which was added this year to the examination programme, 369 candidates were examined, of whom 125 passed. Nottingham sent up this year for the first time 19 candidates in lace manufacture, of whom 13 succeeded in satisfying the examiner.

Examinations were held this year in 43 subjects, as against 37 in 1883, the only subjects included in the programme in which no examinations were held being the Mechanical Preparation of Ores and Salt Manufacture.

Practical examinations were held this year for the first time in weaving and pattern designing, and in metal plate work, and owing to an alteration in the arrangements for the conduct of the Practical Examination in Mine Surveying, the results of the examination in this subject are also included in the accompanying tables.

Of the 23 candidates for honours who, besides undergoing a written examination in pattern designing and weaving, sent up specimens of their work, 13 succeeded in obtaining a certificate. In metal plate work, two candidates presented themselves for honours, but neither succeeded in obtaining the institute's certificate. In all subjects of examination, the honours certificate of the Institute is intended to be regarded as a diploma of proficiency, and is awarded in those cases only, in which the candidate shows a sound theoretical and practical knowledge of the subject.

The percentage of failures on the results of the examinations in all the subjects has increased from 37·5 in 1883 to 49·7 in 1884. This increase in the number of failures is due to many causes, which are referred to in the separate reports of the examiners, prominent among which is the want of skill in drawing, and of previous science teaching on the part of the candidates. In many subjects, too, there is still experienced the serious want of competent teachers, which it is hoped will to some extent be remedied when the Central Institution is in working order.

The large accession to the total number of candidates is due mainly to the increase in the number of candidates in cloth and cotton manufacture, in weaving and in mechanical engineering, and to the addition of the subject of carpentry and joinery to the programme. In 28 subjects there has been an increase in the number of candidates; in nine subjects, chiefly chemicals,

there has been a slight decrease, and in the remaining subjects the number has remained the same.

Table III. shows the proportion of candidates in each subject who have attended classes the teachers of which receive payment on results. By reference to this table it is seen that of the 1829 successful candidates, 1387 were taught in such classes, and of these, 176 have obtained certificates in honours.

Of the 1829 successful candidates, 1362 were examined this year for the first time. Of the remainder, 189, who had previously obtained an ordinary certificate, have this year gained an honours certificate; 98 have gained a higher place in the same grade; 180 have obtained a second class only in the same grade in which they previously passed, or have competed for a prize and failed to obtain it, and their names are consequently not included in the pass list. Last year, the number of candidates who passed the examination, but in the same class and grade as in the previous year, was 128.

A satisfactory feature of this year's examination is the increase, although small, in the proportion of candidates who, having already passed examinations under the Science and Art Department, are qualified to receive the Institute's full technological certificate. Although the returns of the candidates have not yet been verified, it may be assumed that at least 570 of the successful candidates will be entitled to the full certificate. The corresponding number last year was 420, and comparing these numbers with the total number of successful candidates, it will be seen that the percentage of those to whom full certificates will be awarded has increased from 28 per cent. last year to 31·2 per cent. this year.

In several subjects the full complement of prizes has not been awarded, the merits of the candidates not having justified the examiners in awarding them, whilst in other subjects additional prizes have been given. We see that 156 prizes have been granted, including 137 money prizes, 44 silver medals, and 112 bronze medals. Last year 143 prizes were granted, including 129 money prizes, 48 silver medals, and 95 bronze medals.

Looking at the general results of the examination, the large increase in the number of students under instruction and of the candidates who presented themselves for examination, may be considered satisfactory, as indicating the more general desire of artizans and of those engaged in manufacturing industry to take advantage of the opportunities now offered to them of receiving technical instruction. At the same time, the large proportion of failures consequent upon the accession of candidates, the majority of whom are already familiar with the practice of their trades, but possess a very imperfect knowledge of the application thereto of the principles of science, shows the need that still exists of improved and of more systematic technical instruction for those who are employed in factories and workshops.

Although the Royal Commissioners on Technical Instruction, the Report states, have spoken encouragingly of the facilities now offered to artizans of obtaining in evening classes good scientific and technical teaching, it would appear that the number of persons engaged in manufacturing industry, who avail themselves of the Science and Art Classes under the Department, is still comparatively small, and that the proportion of children who learn drawing in the public elementary schools is, as yet, inconsiderable. These causes doubtless prevent our artizans from deriving the full advantage of the Technical Classes now organised in different parts of the kingdom.

In considering the foregoing results, the inadequate supply of competent teachers in technology must also be taken into account.

SCIENTIFIC SERIALS

American Journal of Science, July.—Contributions to meteorology, twentieth paper: reduction of barometric observations to sea-level, by Prof. Elias Loomis. The results embodied in this paper have been determined by an extensive comparison of observations at five mountain stations, three in the United States and two in Europe. The reductions thus obtained were compared with those computed from the theories of Laplace and Plantamour, and exhibited very great discrepancies for all the stations, especially at the lowest pressures. The cause of these discrepancies is referred to the pressure coefficient in the Laplace formula, which appears to be too small.—Light of comparison stars for Vesta, by Edward C. Pickering. The light of the planet is here determined from comparison with the two stars $DM_1 + 22°$ 2163 and 2164, observed with the large meridian photometer of the Harvard College Observatory. The mean result thus obtained for the magnitude of Vesta is 6·64, as compared with 6·49 and 6·45 of previous observations at the same Observatory.—Mineral notes from the laboratory of the United States' Geological Survey, by F. W. Clarke and T. M. Chatard. The paper embodies a complete analysis of the jade or nephrite and pectolite implements in use amongst the Eskimo of Point Barrow, Alaska, and obtained from a region to the east, not yet visited by civilised man. Analyses are also given of Saussurite from Shasta County, California; of Allanite from Topsham, Maine; of Damourite from Stoneham, Maine; of Margarite from Gainesville, Georgia; of Halloysite from near Lake Mono, California; and several other rare minerals.—On the occurrence of alkalies in beryl, by Samuel L. Penfield. The results of numerous investigations show that alkalies are always present, undoubtedly replacing the beryllium, that water is also present, and cannot be disintegrated in the formula, and that the formula

$$Al_4Be_5H_2Si_{11}O_{34}$$

is the one best agreeing with the analyses.—The Niagara River and the Glacial Period, with map, by Prof. G. F. Wright. The author infers that the Niagara River itself has worn the whole of the Gorge, from Queenston to the falls, with perhaps some little help from pre-Glacial erosion above the whirlpool. The rate of erosion, calculated at about 3 feet a year, would make the time required not over 10,000 or 12,000 years.—Note on the discovery of primordial fossils in the town of Stuyvesant, Columbia County, New York, by S. W. Ford. The fossils obtained from the stratified rocks of this region show that they belong to the Lower Potsdam formations. Amongst the species obtained were *Palæophycus incipiens*, *Obolella crassa*, *Stenotheca rugosa*, *Hyolithes Americanus*, *H. impar*, *Hyolithellus micans*.—Notes on some apparently undescribed forms of freshwater infusoria (ten illustrations), by Dr. Alfred C. Stokes. The species named and described are: *Loxodes vorax*, *Apgaria undulans*, *A. ovata*, *A. elongata*, *Heonema dispar*, *Solenatus apocamptus*, *S. orbicularis*.—On the causes of variation of species, by Romyn Hitchcock. The author combats Dr. Carpenter's view, published in the Reports of the *Challenger* Expedition, that variation in the orbolites group is the expression of a not understood "progressive tendency along a definite line towards a higher specialised type of structure in the calcareous fabric." He contends that the highly complex form of shell developed by this simple sarcode organism is not due to any inherent tendency towards a definite plan, but to change of environment and other easily understood causes.—Remarks on the crustacea of the *Albatross* dredgings off Cape Hateras, and thence to the region of George's Banks in the year 1883, by Sidney J. Smith. The whole number of species of Decapoda determined from these dredgings was 72, of which 40 were taken below 500 fathoms, 29 below 1000, 13 below 2000, and 6 at a single haul in 2949 fathoms. Striking characteristics of the deep-sea specimens are their red or reddish colour and distinctly faceted eyes in the normal position, showing conclusively against the arguments of physicists that some rays of light must penetrate to depths of over 2000 fathoms.—Crystallised gold in prismatic forms, by Wm. P. Blake.—Mode of action of shell- and rock-boring molluscs, by Prof. F. H. Storer. The author argues that it is not a drilling or other mechanical action, but a distinctly chemical process, the solvent being probably free muriatic acid.—Memorials of the late George Engelmann and Oswald Heer, Associate Fellows of the American Academy, Botanical Section, by Asa Gray.

Journal of the Chemical and Physical Society, vol. xvi. fasc. 4.—On the action of aldehydes on zinc-organic compounds, and the formation of secondary alcohols, by G. Wagner. Aldehydes of the fatty and aromatic series give, with zinc-ethyl, alcoholates of secondary alcohols, these last being the exclusive, or nearly exclusive, produce of the reaction, which circumstance gives an easy means for preparing secondary alcohols; the speeds of the the reactions are, however, very different. On the influence of temperature on the acceleration of certain reactions, a preliminary communication by M. Menschutkin.—Quantitative determination of zinc in zinc-powder, by Th. Beilstein and G. Javein.—On anhydride of erythrite, by S. Prybitek.—On canarine, a new tinctorial substance discovered by O. Müller, by W. Markovnikoff. It is not soluble in water, spirit, ether, and benzene, but only in bases, according to the strength of which it gives different colours from pale yellow to red.—On anhydrides of

mannite, by A. Sivoloboff and A. Alekhin.—On the structure of the atmosphere and on the general laws of gases (second paper), by E. Rogovsky. The criticism of the author brings him to the conclusion that the kinetic theory of gases must be revised before deducing the hypsometrical formula. The inquiry is to be continued.—On the magnetism of iron wires which are partially inclosed by a magnetising bobbin, by P. Bakhmetieff. The curve which expresses the relations between the magnetic momentum (m) and that part of the wire (l) which is directly submitted to the action of the bobbin has an irregular shape; the fraction $m : l$ reaches a maximum, which is reached sooner when the magnetising force is greater.—On the specific heat of liquids, by A. Nadejdin.—On the theory of dimensions, by N. Sloughinoff.—On a general law of dilatation of liquids, by M. Avenarius.—Remarks on M. Bardsky's paper on the intramolecular force.

Vol. xvi. fasc. 5.—On alizarine oils, by P. Loukianoff. They are found to consist chiefly of basic salts of common fatty and sulpho-fatty acids, the former in greater amount.—On the dependency of photo-chemical phenomena upon the amplitude of the luminous wave, by C. Timiriazeff. On the ground of several observations the author concludes that it is probable that the more energetic reactions are due to waves having a greater amplitude; and that, out of the waves absorbed by a body, those having a greater amplitude act more energetically.—Action of ethylic iodide on the azobenzoate of silver, by P. Goloubeff.—On naphtochinone and its derivatives, by O. Miller.—On the separation of calcium from strontium by Snidersky's method, by J. Bogomoletz.—On triphenylamidomethan, by W. Hemilian and G. Silberstein.—On some salts of mesotartaric acid, by S. Przibytek.—On the heat of magnetisation of a circular magnet, by P. Bakhmetieff. It is much less than in rectilinear magnets, and seems to follow other laws; the development of heat is altogether doubtful in such magnets.—The steam-engine made by Polzounoff in Siberia in 1763, by W. Lermontoff.—Notes on elementary optics.—Note on M. Kraævitch's paper on a hydrodynamic equation, by N. Petroff.—On the dilatation of liquids and its relation to their absolute boiling-points; an answer to M. Avenarius, by D. Mendeleeff, being a few remarks on the history of the subject and on M. Avenarius's logarithmic formula of dilatatiin.

Schriften der Physikalisch-Ökonomischen Gesellschaft, Königsberg, 1883.—On hybrid varieties of the violet; inaugural dissertation, by A. Bethke.—Memorial address on Charles Darwin, by Dr. Richard Hertwig.—Report on the twenty-first meeting of the Prussian Botanical Society at Osterode, October 1883, by Dr. Caspary, President.—Memoir on the latest discovery of the Stone Age in the East Baltic region, and on the beginning of plastic art in North-East Europe, by Dr. Otto Tischler.—On the sources whence plants derive their nourishment, by Dr. Klien.—Report on the expedition to Aiken to observe the transit of Venus, by Dr. Franz.—On some disputed questions connected with the anatomy of the eye, by Dr. Schwalbe.—On the degrees of sensitiveness in living substances, by Dr. Grünhagen.—On abnormal vision, by Dr. Richard Hilbert.—On the geology of the region between Elbing and Dirschau.—On the primeval history of the Caucasus, by Dr. Otto Tischler.—Anatomical description of the cinnamon plant, by Prof. Sanio.—On the microscopic Algæ and spores of the Russian coal-measures, by Prof. Robert Caspary.—Anatomical and physiological remarks on the wasp family (*Nematus pollipes* and *N. rufipes*), by Prof. Gustav. Zaddach and C. G. A. Brischke.—Description of a new myograph for measuring the velocity of the nervous processes, by Prof. A. Gruenhagen.—On subjective impressions of colour, by Dr. Berthold.—On some new and rare plants found in Prussia, by Prof. Caspary.—On the fossil fishes in the provincial museum, by Dr. Jentzsch.—On the Jurassic system of the Inovrazlav district, by Dr. Jentzsch.—On the site of the Oracle of Dodona, by Dr. G. Hirschfeld.

Atti della R. Accademia dei Lincei, April 20.—Report on the archæological discoveries made in various parts of Italy during the month of March, by S. Fiorelli.—On the normal annual recurrence of certain meteorological phenomena deduced from the observations made at the Collegio Romano, by Pietro Tacchini.—Note on the equilibrium of elastic and rigid surfaces (continued), by S. Betti.

May 4.—Inaugural address by the new President, Cavaliere Francesco Brioschi.—Obituary notice of M. Dumas, by S. Cannizzaro.—On the relations existing between the refrangent power and chemical constitution of organic substances, by Drs. R. Nasini and O. Bernheimer.—On the groups of the series of $a, b \ldots k$ dimensions, by Giovanni Frattini.—Observations of the new planet 236 between Mars and Jupiter, made at the Observatory of the Collegio Romano, by Elia Millosevich.—Observations of the Pons-Brooks comet made at the Observatory of the Campidoglio, by Francesco Giacomelli.—Remarks on the declination and horizontal composition of terrestrial magnetism in Rome during the last ten years, by Filippo Keller.—Influence of magnetism on the embriogenesis and sterility of the ovum, by Carlo Maggiorani.—Meteorological observations at the Observatory of the Campidoglio during the month of March.

Rendiconti del R. Istituto Lombardo, June 19, 1884.—The concept of linear length is independent not only of the idea of derivation but also of that of continuity, by Prof. G. Ascoli.—A contribution to the study of the Northern Apennines, by Prof. T. Taramelli.—On the representation of the Newtonian forces, by means of the elastic forces, by Prof. E. Beltrami.—On the integration of the differential equations of the conic pendulum, by Dr. Gian Antonio Maggi.—On the revival of the critical philosophy of Kant, by Prof. C. Cantoni.—Note on a poem of Alessandro Volta in honour of Saussure's ascent of Mont Blanc in 1787, by Zanino Volta.—Meteorological observations made at the Brera Observatory, Milan, during the month of May.

July 3.—New measurements of the planet Uranus, by Prof. G. V. Schiaparelli.—Researches on the alkalis of the blood and their variations in intensity artificially produced; physiopathological and therapeutic importance of these experiments, by Prof. C. Raimondi.—Integration of the differential equation $\Delta^2 u = 0$ in the area of a circle, by Prof. Giulio Ascoli.—A pathological study of the cellules and parasites in the animal system, by Prof. G. Sangalli.—Meteorological observations made at the Brera Observatory, Milan, during the month of June.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, August 4.—M. Rolland, President, in the chair.—Reply to two notes of M. Wroblewski on the subject of the liquefaction of hydrogen and other gases, by M. L. Cailletet.—On the influence of temperature on the property of absorbing and losing moisture, possessed by vegetable earth and other substances exposed to contact with the atmosphere, by M. Th. Schlœring.—On the change in the excentricities of the planetary orbits due to the concentration of matter in space, by M. Hugo Gyldén.—Report of Messrs. Gosselin, Vulpian, Marey, Bert, Pasteur, Richet, Bouley, and Charcot on various communications received by the Academy on the subject of cholera. An examination of forty-three letters, notes, and memoirs has led to no results calling for special consideration. The chief remedies proposed are hypodermic injections of chloride of pilocarpine, the internal application of sulphate of quinine, of oxygenated water, sulphuric lemonade, &c. More important are the views of Dr. Duboué of Pau, who recommends as a preventative the strengthening of the endothelial and epithelial systems by the daily administration of two doses of 0·25 grain of pure tannin prepared with ether. His curative method consists in restoring the circulation by copious intravenous injections of an artificial serum to which should be added one grain per litre of pure tannin.—Observations of the Barnard comet made in Algiers, by M. Trépied.—Note on the distribution of the facules on the solar disk during the year 1883, with tabulated results, by M. P. Tacchini.—Description of a fixed astronomic telescope, being a modification of M. Lœwy's "*equatorial coudé*," by M. G. Hermite.—An account of the method by which the absolute value has been determined of the horizontal component of terrestrial magnetism at the observatory of the Park Saint-Maur, Paris, by M. Mascart.—Description of a new apparatus for collecting the snow of carbonic acid required in producing low temperatures (one illustration), by M. Ducretet.—On the decomposition of white cast iron by heat, by M. L. Forquignon.—Note on the composition of the cyanides of mercury, zinc, and of some other elementary compounds of cyanogen, by M. G. Calmels.—On the nature of the visual faculty, and on the respective parts played by the retina and the brain in the elaboration of optical impressions, by M. H. Parinaud.—Researches on the biological *rôle* of phosphoric acid, and on the part played by this

substance in the formation of the animal tissues, by M. A. Mairet. —On the permanent immunity from charbon of rabbits vaccinated with the attenuated virus of this disease, by M. Feltz. Seven months after the vaccination six rabbits so treated and six others were operated on with a strong preparation of the virus. The six fresh animals all died of charbon, while the six that had been vaccinated remained unaffected by the second operation. But when again treated, eighteen months afterwards, they yielded to the virus, and all ultimately perished. The author infers that the operation preserves its efficacy in the rabbit not longer than eighteen months.—Description of a filter which yields absolutely pure water free of all animal life, by M. Ch. Chamberland.—On the anatomical origin of spermaceti; description of the so-called spermaceti case, by MM. Pouchet and Beauregard.—Memoir on the carboniferous measures of the Central Pyrenees, by M. L. Lartet. —On the composition and quality of coal in connection with the nature of the plants from which it has been formed, by M. Ad. Carnot.—On the oxychloride of calcium, and the simple and chloruretted silicates of lime, by M. Alex. Gorgen.—On the origin of the phosphorites and of the ferruginous clays in limestone districts, by M. Dieulafait.—Account of the effects produced by a stroke of lightning at Campan on July 24, by M. A. Soucaze. A house near the telegraph station was entered through the closed door by a living mass of flame, which, after a few seconds withdrew by the same way without injuring any of the inmates or damaging the furniture.—A hypothesis on the temperature of the zone of the solar protuberances, by M. Tardy. The author suggests that in this zone the hydrogen is rendered luminous by an atmosphere of oxygen, in which case the temperature would be that of the fusion of platina, while the temperature of the inner zone would be still higher.

BERLIN

Physiological Society, July 18.—The conception that, just as the chemical elements in *status nascendi* are characterised by greater energy of action than in the ordinary state, so also in the living organism the substances in process of generation and development would exhibit a different or more intense action than substances already fully formed, has been subjected to an experimental proof by Dr. Falk. He first made an examination in the case of prussic acid. A dilute mixture of emulsin and amygdalin, which yielded prussic acid both outside as well as in the body, was divided into two halves, one being injected by a syringe, immediately after the process of mixture, subcutaneously or directly into the sanguineous channel of one of the animals operated on, the other into that of the other animal intended to serve the purpose of comparison, but not till twenty-four hours after the process of mixture, and therefore after all the hydrocyanic acid had become completely formed in the solution. In both cases the phenomena of poisoning occurred, produced by the prussic acid. In the first case, however, in which the prussic acid was developed in the organism, the phenomena of poisoning occurred always at a later stage and in a milder form than in the second case, in which the prussic acid was administered when it was already completely formed. The second substance examined by Dr. Falk was the oil of mustard, which was produced from the myrosin and myronic acid salts contained in black mustard. The experiment in this case was performed in the same manner, and yielded a similar result, as in the former case. Thirdly, an experiment was instituted with hydroquinine, which was formed from arbutin; and here, too, the substance acted more weakly and slowly when it had first to develop itself in the body. From these experiments Dr. Falk drew the conclusion that substances in process of formation, or in the so-called *status nascendi*, possessed no peculiar or greater activity than in the ordinary state.—Prof. Kronecker spoke of a series of precautionary measures to be observed in cases of saving life by an infusion of common salt solution. He first described how animals after severe loss of blood recovered in the best and most rapid manner by introducing into their blood-channels a like quantity of physiological common salt solution. In the case of infusions of albuminous solutions, of serum sanguinis, and even of the blood of another individual of the same species deprived of its fibrin, there was, according to direct measurements, an invariable destruction of blood-corpuscles. With infusions of common salt solution, on the other hand, blood-corpuscles were seen to increase somewhat rapidly. Prof. Kronecker then proceeded more particularly to lay down precautionary rules to be observed in applying this agency to man. In the first place, the composition of the solution must be such as was most compatible with the human organism. It would appear that a solution of 0·73 per cent. exercised the least irritation on the human body, and was therefore the most appropriate for infusions designed to save life. The addition of carbonate of alkali, recommended by some, had an injurious effect. Of great importance were the velocity and pressure with which the infusion was injected; both ought to correspond with the velocity and pressure in the vein into which the solution entered. The common salt solution should, further, be disinfected beforehand by boiling, and the air which penetrated into the reservoir while it was being emptied must be filtered off by means of a wadding stopper. The injurious effect of too strong pressure was illustrated by a comparative experiment on two rabbits.—Dr. Krause reported some attempts towards the experimental production of contractions of the vocal chords. The possibility he had demonstrated on a former occasion, by pulling forward the tongue and pushing back the epiglottis, of observing the vocal chords of dogs by daylight, facilitated these experiments in a very considerable degree. He applied a prolonged, weak, mechanical stimulation of the nervus recurrens or vagus. A thin slice of cork having, by means of a piece of catgut, been loosely wound together with the nerve so as to exercise on it a continuous moderate pressure, he observed, about the second day of the experiment, the vocal chords under inhalation lie close to each other, and only under exhalation form a small opening between each other. This continuous closure of the glottis was followed, in about four to five days, by a paralysis of the chords, which lasted to the death of the animal. Sections showed in the first stages of the experiment reddening of the nerve and infiltration of the surrounding tissue; later on were found inflammation and extravasation in the nerve; and ultimately molecular decay of the nerve-fibrillæ. The closure of the glottis during the continuance of a prolonged moderate pressure on the recurrens or vagus was explained by Dr. Krause as a contraction of the laryngeal muscles, of which the stronger sphincters of the glottis obtained the preponderance. That the contraction occurred only the second day after the operation was effected, according to the ideas of the speaker, in this way: that the moderate pressure in the normal nerve produced no stimulation beyond what caused the minimum of irritability, and that only after the nerve had become inflamed by the pressure did that pressure suffice to produce a contraction of the muscles and to maintain it till the destruction of the nerve-fibrillæ brought about a paralysis.

TECHNICAL INSTRUCTION[1]

II.

IN a former article the Report of the Royal Commissioners on Technical Education was reviewed so far as relates to the technical schools and colleges of the Continent. The present article deals only with that part of the Report which relates to the United Kingdom.

In the Report of the Royal Commissioners we have a very careful and full account of the various colleges and technical schools that are in existence at the present time. The condition and history of each of these institutions has been thoroughly looked into, and their importance has been fully estimated.

After having passed in review all the important institutions of this kind, the Commissioners devote an exceedingly important part of their Report to conclusions which they have drawn up from the facts placed before them in their various inquiries.

The early part of this chapter is devoted to comparing the development of the various industries both at home and abroad. The fact is pointed out that we were practically the sole possessors of modern appliances until the early part of the present reign, when the Continental nations, settling down to peace after troubled times, found that to compete in any way with us they must give every facility to the then rising generation to improve their position. For this purpose, as was shown in the previous article, technical or polytechnic schools were instituted in most of the Continental States. It is within this period that most of our present institutions for technical education have sprung into existence; but now, on all hands, we find that the advantages obtained from these are acknowledged both by those who directly benefit by their teaching and by manufacturers, who are able to advance the perfection of their products through the higher state of education of those serving under them.

One great aim of the Technical Commissioners has been to examine into the condition and systems of working of these institutes, and in this point they have to be congratulated upon the care and thoroughness with which they have sought and grappled with the weak points of the present system of education. Not only have the Technical Commissioners so carefully considered the defects in our system of education, but they have just as laboriously and skilfully offered suggestions and made recommendations of reform which it is only right that the nation should insist on being carried out.

One of the first weak points noticed is that almost all the colleges and technical schools stand in need of funds to enable them to cope with the demand made upon them for larger teaching staffs, greater accommodation, and better equipment in their art departments, laboratories, and workshops. Another great need that is pointed out, is the non-existence of modern secondary schools, which are necessary to give a preliminary training to students before entering one of the higher colleges or technical schools, where they can continue their study side by side with their practical work. In this case the Commissioners are of opinion that this, the greatest defect of our system, should be made a matter of legislation, and that local governing bodies should be empowered to found technical and secondary schools wherever necessary.

In discussing the value of the existing colleges the Technical Commissioners remark that "It is most praiseworthy on the part of the professors and teachers that they devote themselves to the important work of tuition for salaries so small as those which they as a rule receive, when many would, by employing their scientific and technical knowledge in private enterprise, obtain much larger pecuniary remuneration." This is of course a fact due in most cases to the lack of funds in such institutions, and in all probability would be considerably remedied if they were relieved from this trouble.

Again, in discussing this same question the Commissioners are of opinion that all colleges do not need to be of the highest type, but of those that are, they say:—"It is, however, of national importance that these few should be placed in such a position of efficiency as to enable them to carry out successfully the highest educational work in the special direction for which the circumstances, particularly of locality, have fitted them; your Commissioners believe that no portion of the national expenditure on education is of greater importance than that employed in the scientific culture of the leaders of industry." Surely the Commissioners could not have spoken plainer. They have without doubt placed on record the fact that such colleges are necessary for the increase of education; and that as yet they are not sufficiently well supported to carry on the duties intrusted to them to their fullest extent.

Two points are well worthy of note in reference to instruction in elementary schools. The Commissioners call attention to the fact that on the Continent *drawing* is an obligatory subject and is held as of equal importance with writing; this is a point which seems to have impressed them, because they are of opinion that "instruction in the rudiments of drawing should be incorporated with writing." This is a point referred to repeatedly in the Report, and great importance is attached to it, as will be seen by the recommendations quoted below.

The second point is the employment of a special science teacher, as at Liverpool and Birmingham, who devotes his time to going round to the various schools giving sound scientific instruction; each lesson being repeated during the week by the schoolmaster.

The whole Report is one mass of useful information, and the suggestions and recommendations which it contains are very valuable. The following are among the most important recommendations quoted at the close of the Report:—

I. As to public elementary schools:—(*a*) That rudimentary drawing be incorporated with writing as a single elementary subject, and that instruction in elementary drawing be continued throughout the standards. That the inspectors of the Education Department, Whitehall, be responsible for the instruction in drawing. That drawing from casts and models be required as part of the work, and that modelling be encouraged by grant. (*c*) That, after reasonable notice, a school shall not be deemed provided with proper "apparatus of elementary

[1] Continued from p. 358.

instruction," under Art. 115 of the Code, unless it have a proper supply of casts and models for drawing.

II. As to classes under the Science and Art Department, and grants by the Department:—(a) That school boards have power to establish, conduct, and contribute to the maintenance of classes for young persons and adults (being artisans) under the Science and Art Department. That, in localities having no school board, the local authority have analogous powers.

IV. Secondary and technical instruction:—(a) That steps be taken to accelerate the application of ancient endowments, under amended schemes, to secondary and technical instruction. (b) That provision be made by the Charity Commissioners for the establishment, in suitable localities, of schools or departments of schools in which the study of natural science, drawing, mathematics, and modern languages shall take the place of Latin and Greek. (c) That local authorities be empowered, if they think fit, to establish, maintain, and contribute to the establishment and maintenance of secondary and technical (including agricultural) schools and colleges.

V. Public libraries and museums:—(b) That museums of art and science and technological collections be open to the public on Sundays.

COTTERILL'S "APPLIED MECHANICS"

Applied Mechanics: an Elementary General Introduction to the Theory of Structures and Machines. By James H. Cotterill, F.R.S. (London: Macmillan and Co., 1884.)

AMONG the many indications of the increasing interest which technical education, in its widest extent, now calls forth, one of the most conspicuous is the production of manuals and text-books on the various subjects with which it deals. Amongst these there is none which is more important than Applied Mechanics, and, at the same time, we may add that there is none which has been more in need of a good elementary textbook. The great works on the subject by Rankine and Moseley are not adapted for elementary teaching, involving mathematical processes beyond the power of a beginner, and thus it has come to pass that a country renowned for its engineering triumphs and for the excellence of many treatises dealing with the practical applications of applied mechanics, has hitherto possessed no book devoted to an exposition of its principles and suitable for educational purposes. Those persons, therefore, who are familiar with Prof. Cotterill's work on the Steam-Engine will have looked forward with much interest to the publication of his long-advertised book on "Applied Mechanics." Its recent appearance we venture to think has in no sense disappointed their expectation, for it bears on every page evidence that its author has not only studied and become intimately acquainted with his subject, but that he possesses the rare faculty of having learned by experience in teaching, the best way of presenting a subject so as to diminish its difficulties and make rough places smooth for the footsteps of the beginner. By assuming a knowledge on the part of the reader of the elements of theoretical mechanics he has been enabled to devote the whole of this large volume to the exposition of the more complicated science, in which the principles of the former are applied to the problems of construction presented to the architect and the engineer. The treatise is strictly elementary in its methods, the mathematics used being, almost without exception, of the simplest kind, and many results, which have usually been obtained by complicated investigations, are here arrived at by neat and elegant simple processes. The style of reasoning adopted is also very successful, being neither too diffuse, nor, on the other hand, so much compressed as to puzzle and dishearten the beginner by gaps in the reasoning which his mental capacity is not able to bridge. This is particularly evident in the earlier parts of the book. Towards the end, in the section on Hydraulics and Pneumatics, we think that sufficient fulness of explanation has hardly been furnished, in dealing with the application of the principles of Energy, Momentum and Moment of Momentum, to Fluids, and especially in the case of Hydraulic Motors, to enable the student to grasp the subject without a frequent reference to some of the text-books which the author names.

Another point of supreme importance in which Prof. Cotterill's treatment leaves nothing to be desired, is the manner in which he has attained the aim he set before himself of endeavouring "to distinguish as clearly as possible between those parts of the subject which are universally and necessarily true, and those parts which rest on hypotheses more or less questionable." In Applied Mechanics it frequently, we may say usually, happens that, owing to various disturbing causes, exact investigations are either impossible to effect or useless from a practical point of view when carried out, owing to the complexity of the results, and we are therefore led either to adopt results derived from experiments conducted under the guidance of a roughly approximate theory or obliged to rely on experiment alone and, in studying the subject, it is of prime importance that the exact limitations should be stated under which the formulæ and rules given can with certainty be applied. This exact knowledge is necessary not only in the interests of science, but also in many practical applications involving the security of life or property. Many writers on this subject have slurred over or insufficiently estimated the importance of an exact statement of conditions and limitations, and consequently we are glad to recognise and point out the thorough and satisfactory way in which this has been attended to by the author.

The book is divided into five parts, of which the first is devoted to "The Statics of Structures." In this section there is not room in an elementary work for much new matter, but we may point out as specially good the manner in which the communication of stress from part to part of a compound frame is traced out. The relation and interdependence of the primary and secondary trusses of such a structure is here indicated more clearly than in any work with which we are acquainted.

The principal peculiarity of the book consists in the complete adoption of Reuleaux's Kinematic Analysis as the basis of the description and treatment of machines, both in their kinematic and kinetic aspects. In this system a machine is regarded as consisting "of a number of parts so connected together as to be capable of moving relatively to one another in a way completely defined by the nature of the machine. Each part forms an element

of two consecutive pairs, and serves to connect the pairs so that the whole mechanism may be described as a chain, of which the parts form the links. Such a series of connected pieces is called a kinematic chain." It is in this mode of regarding the component parts of a machine and in the consequences that flow from it that the peculiarities of the modern system consist. A valuable feature of this work is the series of curves of velocity given for different mechanistic combinations, especially those derived from the slider-crank chain. The special use of such curves is that the varying motion of different parts is exhibited to the eye, which is thus enabled to realise its changes during the cycle in a complete way which would otherwise be difficult, if not impossible. Of the large and intricate subject of the Teeth of Wheels only a sketch is given, which a student would need to supplement by extensive reference to other books in order to understand.

In the Part on the Dynamics of Machines we find the chapter on "The Dynamics of the Steam-Engine" the best in the book. The mode of constructing curves of crank effort of two kinds is shown, and the results given in different cases for two cranks at right angles and for three cranks at angles of 120°, and these curves are used to determine the fluctuation of energy in a complete revolution. This last is expressed in terms of the total energy as a fraction which, in the case of a three-throw crank with connecting rod equal in length to six cranks is as low as ·0084. A method is afterwards given by which to obtain similar results from any indicator diagram.

The chapter on Friction contains a complete *résumé* of modern experiments on friction with an investigation by both exact and approximate methods of the efficiency of mechanism when friction is considered.

The Principle of Work is assumed throughout the book, being regarded as "a fundamental mechanical principle continually verified by experience, and a great many results are thus arrived at in the simplest way. One very interesting example is got by applying this principle (in the form known as the principle of virtual velocities) to the determination of the bending moment in the case of a loaded beam. Nowhere has the author been more successful in his simple mathematical treatment than in the chapters which deal with the strength and deflection of beams, and the power possessed by a combination of the mathematical and the graphical methods could hardly be shown more strongly than by the proof, given without the use of the calculus, of the most general form of Clapeyron's Theorem of Three Moments.

The fundamental theorems of the theory of elasticity are presented in an equally simple and elementary way. In describing the behaviour of matter strained beyond the elastic limit, a brief account is given of the mode of rupture of different classes of bodies when loaded so as to exceed that limit, and the information here furnished, as in all the other descriptive parts of the book, is brought up to the level of our present experimental knowledge.

The concluding chapters treat of the transmission and conversion of energy by fluids, and contain a brief account of the ordinary propositions in hydraulics and pneumatics, together with the outlines of the theories of hydraulic motors and of heat-engines. The flow of liquids and gases through pipes is also dealt with.

The aim of the book excludes any detailed description of machines, although the drawings of machines are, as a rule, working drawings, the desire being to elucidate the principles and theory of machines in general, but incidentally much valuable descriptive matter is introduced, and the illustrations are in all cases derived from actual machines and structures. Thus, among other valuable topics of practical interest we have an exposition of the theory of fly-wheels, centrifugal regulators, dynamometers, the balancing of machines, and of impact, this last being illustrated, amongst other examples, by the action of a gust of wind on a vessel.

At the end of each chapter we find a selection of well devised and admirable examples, most of them so framed as either by way of illustration to bring into prominence particular parts of the text or to show the influence in special cases of modifying causes. This collection, which must have taken much time and trouble to prepare, is by no means the least useful part of the book, the value of which is yet further increased by the full list of authorities for reference which is appended to each chapter, which will assist the student in extending his studies in any special direction.

This book may be recommended not only for the admirable mode of treatment of that which it contains, but also for the exclusion of that which does not find a place there. The same knowledge of the needs of a reader beginning the study of applied mechanics which has led to the selection and arrangement of the topics introduced, has led to the omission of other parts which, though useful and interesting in themselves, are not necessary to be mastered on a first approach to the subject. We could wish that the proofs had been more carefully revised, so that a number of, for the most part trifling, though tiresome, errata might have been corrected. A careful perusal of the volume leads us to express almost unqualified praise of this latest addition to the English literature of applied mechanics.

J. F. MAIN

OUR BOOK SHELF

Graphic and Analytic Statics in Theory and Comparison. By Robert Hudson Graham, C.E. (London: Crosby Lockwood and Co., 1884.)

THIS is an extensive treatise for the use of engineers, the distinguishing feature of it being that graphic and analytic methods are both employed. The first part (30 pp.) deals with the principles of graphic statics, and contains some well-chosen examples of the beautiful method of reciprocal figures. The second part (50 pp.) treats of the stresses of roofs and bridge structures, both methods being employed. The third part (290 pp.), which for some reason is called comparative statics, consists of eight chapters, the subjects of which are direct stress (elongation of bars, &c.), couples, composition of forces, centre of gravity, moments, straight beams and girders, solid girders in equilibrium, and wind pressures. Throughout the book there are interspersed collections of valuable exercises with their results.

The most manifest defect of the work is a prevailing inaccuracy of expression. With such a subject this is quite inexcusable, and is sure to be found excessively trying to the patience of a student. It is not at all due to want of mathematical knowledge on the author's part, so that, as might be expected, he is perfectly unconscious of it. Ludicrously so indeed; for in the preface he tells us

that "the language used has been carefully studied with a view to simplicity and clearness," and explains how there came to be in his eye such a mote as "*angular*-point," without making the most distant reference to a store of *beams* sufficient for a rather massive engineering structure.

The choice and arrangement of the matter, too, cannot be commended. Elementary integrations are performed at full length, which may be done by the reader himself if he knows anything of integration, and which are useless if he does not. The expression for the radius of curvature in terms of dy/dx and d^2y/dx^2 is used at p. 252, and it is not until forty pages farther on that we find the usual elementary explanation of rectangular co-ordinates, the construction of a curve from knowing simultaneous values of x and y, and the meaning of dy/dx. This defect is really not distinct from the other: both are the consequence of a certain logical haziness of mind which may not, and we believe does not, detract from the author's skill as an engineer, but which is certain to be fatal to his success as an exponent of engineering science.

Had the main matter of the book been worthless or commonplace it could have been summarily dismissed; but there is so much evidence in it of ability and power of work that one eagerly wishes to see the style and structure of it improved. We trust a second edition may be called for, and that for the preparation of it the author may be induced to associate himself with some one having the necessary logical clearness and pædagogic skill to make it what it might easily be—an admirable text-book.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

School Museums

While the very valuable display of educational appliances is still on view at the Health Exhibition, I should like to draw attention to the school museums which are becoming now an important element in the teaching of science. In Mr. Lant Carpenter's papers they were only slightly alluded to, though he did full justice to the technical exhibits. In the recent Instructions to Her Majesty's Inspectors it is laid down that an infant school which deserves to be considered "excellent" and to receive a corresponding merit grant should have a cabinet of objects which it is suggested should be partly collected by the children themselves. This of course is making teachers anxious to form such collections, and the London School Board supplies a cabinet wherever there is a promising nucleus for such a museum; it also supplies to any teacher that desires it a small box of chemical apparatus for making simple experiments on these objects, with instructions for the use of the different pieces of apparatus. One of these sets of apparatus forms part of the exhibit of the London Board. Of course the collection of the infants' department will be of a miscellaneous character, but in the museums that are now being formed in many of the boys' and girls' departments something better may be aimed at. The School Cabinet in Room No. 4 is filled principally from the schools in the neighbourhood of South Kensington. There are stuffed birds and a small crocodile, together with neatly-mounted skulls of animals, and specimens of corals, shells, and sponges, all from the collections at Park Walk, Chelsea. From other schools there are the skeleton of a rabbit dissected by a boy of eleven years of age, insects, reptiles, and other objects. There is also a collection from the Silver Street School at Kensington, contributed by scholars, teachers, and managers, comprising colonial products of various descriptions, specimens of different kinds of wood, many of them cut from the trees blown down by the great storm that was so destructive in Kensington Gardens in the autumn of 1881. There are also specimens of horseshoes with their appropriate nails, and illustrations of the successive processes in the manufacture of iron, cotton, and jute. These are all properly named and labelled by the schoolmaster. The lowest shelf of the cabinet contains illustrations of the geology of Peckham, ranging from the sands and gravels of the ancient Thames, the London Clay, the Woolwich and Reading beds, and the Thanet Sands, down to the Chalk. These form part of a fine collection at the Nunhead Passage Board School, Peckham. From the same school also there is a separate cabinet of minerals, which is displayed in the corridor. Some of the training colleges have formed good museums, as is evidenced by the collection from the Wesleyan College in Westminster.

In the further development of these museums two things may well be borne in mind:—(1) In addition to the more miscellaneous collections got together by the children and friends of the school, there should be supplied typical specimens for more systematic instruction. The Japanese exhibit such a collection of zoological types. (2) The special industries of the neighbourhood should be well illustrated in these museums. That this is well carried out in France and Belgium is shown by the contributions to the Exhibition from these countries, and especially by that of the Brothers of the Écoles Chrétiennes.

At the Educational Conference an afternoon was devoted to this subject. Dr. Jex-Blake described a Museum of Science and Art which has been formed at Rugby School, and in the discussion which followed particulars were also given of the loan collections for schools now being organised by the Liverpool School Board, of the Communal Museums, which are an important development of the French School Museums, and of a large Educational Museum which has lately been organised at Madrid. All these show the gradual, but sure, advance which is being made all along the line in the objective teaching of natural science.

August 14 J. H. Gladstone

The Red Glows

I have recently been staying at Zermatt and have observed the great corona or circle round the sun mentioned by your correspondent, Mr. T. W. Backhouse, in Nature for August 14 (p. 350). It was very distinct on July 29, both at Zermatt and on the Garnergrat, and likewise on the four following days. On August 3 rain fell in the evening, but the night became cloudless; on the 4th the corona had gone. I noted the following points:—(1) The colour of the circle was like the red of clean copper when it has become coated with suboxide; this faded away into what appeared brown against the blue sky. (2) Immediately surrounding the sun and between it and the circle the sky was blue. (3) The spectroscope directed towards the blue sky or a white cloud showed a complete absence of the bands lying near B, C, and D, which indicate the presence of water vapour. (4) A band appearing like a broad line was observed between D and E, distinct, but of lesser density than it usually appears at lower elevations. (5) There did not appear to be any marked difference in the intensity of the colour of the corona when viewed on the same day at altitudes varying between 6000 and 10,000 feet. (6) After rain had fallen on the evening of August 3 the almost cloudless sky altered in appearance; in that part close to the sun it appeared whitish, and the whiteness diminished as the distance from the sun increased, until it had faded away into blue. (7) On occasions when there were fleecy clouds in the sky during the visibility of the corona, the clouds as they approached the corona appeared of a pale but very vivid green. This colour effect was due to contrast.

Savile Club, August 15 W. N. Hartley

Remarkable Raised Sea-Bed near Lattakia, Syria

In reference to the changes which have taken place along the coast of Syria and Palestine in recent times, the following letter from Dr. Post, of the Syrian Protestant College, Beirût, descriptive of beds of shells now living in the Mediterranean may prove of interest. Edward Hull

Geological Survey Office, Dublin

On a Deposit of Marine Shells in the Alluvium of the Lattakia Plain, in Syria

The Plain of Lattakia extends from Jeblah, a few hours south, to the chalky ridge which forms the southernmost of the roots

of Mount Cassius, and separates it from the first of the valleys of that chain, the Wadi Kondil; and from the Mediterranean on the west to the Nusairy Mountains on the east. A little to the north of Lattakia the plain juts out into the sea, in the Ras Ibn Hani. The portion of the plain north of Lattakia is low, flat, and separated from that lying east and south-east of the town by a low ridge which divides it from the valley of the Nahr-el-Kebîr. The eastern and south-eastern portion of the plain is traversed by three streams, flowing south-south-west from the Nusairy Mountains, and emptying into the Mediterranean east of the meridian of Lattakia. The first of these is the Nahr-el-Kebîr, the second the Nahr-el-Snowbar, and the third the Nahr-el-Beidha. The surface line of the plain rises gradually from the western limiting ridge of the Nahr-el-Kebîr to the base of the mountains, about five hours (by camel) east of Lattakia. The plain, however, in this portion is so channelled by the deep valleys of the above-mentioned streams and their affluents that it can only be called a plain with reference to an ideal surface tangent to the tops of its hills, or rather ridges, which occupy but a small portion of the total area. The height of the ridges near the centre of the table-land is about 350 feet, and increases gradually, with each successive ridge, until the foot of the mountain is reached. The flanks of these ridges are steep, often at an angle of 45°, and the bottoms of the main streams on the parallel of Lattakia are about 100 feet above the sea.

The soil of this table-land is a tenacious clayey loam, the product of alluvial deposit from the streams which now flow through its valleys. The deposits of marine shells are found at various points in the valleys of all three of the streams flowing through this plain. In my recent visit to some of these localities with Dr. Dodds of Lattakia, my aim was rather to survey the general character of the sites and the nature of the deposits than to make an exhaustive collection of the species, which would require much time and labour.

The nearest locality is in the basin of the Nahr-el-Kebîr, about an hour and a half north-east of Lattakia. Dr. Dodds has visited it, and found it less productive than that which we chose for our search. Our route lay nearly due east from Lattakia to a village called el-Qutrûjeh, three hours away from the town. At a distance of about an hour and a half from Lattakia we came upon a detached mass of conglomerate, the clay of which was barely solidified, containing many of the species of shells and corals which we afterwards found loose in the soil. The mass was about two feet long by a foot broad and six inches thick. It was the only one we found, and the only one found by Dr. Dodds in all his journeys through this plain. Near it were many detached shells, but of two or three species only. The most productive locality is the sides of the ridges east of el-Qutrûjeh. What seems most curious is that the shells are almost all found between the levels of 150 and 250 feet (measured by the aneroid). We found few above 250 feet, and those below that level were manifestly carried down by water.

The shells are found loose on the surface of the soil, or projecting from the steep slope of the hillside, associated with recent snail-shells. In a subsequent article I hope to give the names of the species found.

So far as I know, no similar deposit has been found in the alluvium of Syria. In a recent journey through Northern Syria we searched in vain for any traces of marine shells in the western portion of the Lattakia Plain and the valley of the Orontes. I have never seen them in the plains of Akkar, or Esdraelon, or Sharon. GEORGE E. POST

A Carnivorous Wasp

A FEW days ago a wasp, which had created some mild excitement by sailing over our luncheon-table, was observed to seize a fly which was on the back of an arm-chair. It settled on the fly, and when I came to look at the butchery—for I cannot call it a fight—the poor fly was minus its head, and I was in time to see one of its wings fluttering down to the ground. The wasp was stretching over its victim and holding him as a spider might do, and on my approach he spread his wings and carried off the body to the other end of the room, presumably to eat it. Both the wasp and the hou efly seemed to be of the common sort which have given so much trouble to the Queen's lieges in this hot weather. I never heard before of a wasp that imitated the habits of a spider. Could you tell me if this is an ordinary thing, or whether it was merely an individual eccentricity of this wasp? F. N.

August 16

Intelligence of a Frog

LAST night I rescued a frog from the claws of a cat, and, to my great surprise, it turned, and, after gazing at me for a few seconds, jumped slightly towards me, halting after each leap and looking up into my face. It thus gradually approached, and in about two or three minutes had actually climbed upon one of my feet. Its mute appeal for protection was most remarkable, and could not possibly be misunderstood. R. R.

Lawton, August 15

Meteor

LAST night, about 10.20 p.m., I happened to see a meteor worth recording. It moved horizontally, from south to north, across the middle of the western sky) about half way down from the zenith. The sky was cloudless: had that sky not been flooded by the light of a moon that was scarce on the wane, and that extinguished all but very few stars, the meteor would, no doubt, have been a brilliant phenomenon; under the circumstances its splendour was much dimmed. Its course was indicated by a series of small sparkling spangles, which flashed forth beautifully amid the gold-gray glow; the intermission of its lustre is a noteworthy fact. J. HOSKYNS-ABRAHALL

Combe Vicarage, near Woodstock, August 8

Podalirius minutus

IN Prof. Mayer's recent work on the Caprellidæ ("Fauna u. Flora des Golfes Neapal") there is a species figured and described as *Podalirius minutus*, in which the anterior of the three posterior pairs of thoracic appendages are very minute, contain only two joints, and are attached about midway between the two ends of the segment which bears them. With this marked exception this species agrees very closely on all points with *Caprella lobata* and *C. linearis*. My object in drawing attention to it is to ascertain if it has been recorded as a member of the British fauna. H. C. CHADWICK

SCALES

SCALES, as used by the architect and surveyor, may be roughly divided into two classes. In the first we have scales of equal parts, in the second scales of unequal parts, by means of which results may be obtained which otherwise would require more or less calculation. The fundamental idea of a scale of equal parts is that any assigned magnitude may be represented by a line of determinate length, and that thus any relation between magnitudes of the same kind may be indicated by a relation between lines in the same ratio. The simplest form in which they can be used is to represent in an enlarged or diminished size the magnitude of a length, as when, for instance, a mile is represented by an inch. By altering in two rectangular directions the magnitude of an area, we obtain a plan of it in which the scales used may be different for the two directions, as when the cross-section of a stretch of country has one scale for horizontal distances, and a different scale for vertical heights.

By introducing the system of coordinates, and representing, according to selected scales, the magnitudes of two or three related and dependent quantities, by lengths measured in two or three perpendicular directions, we are able to represent by geometry the connection between those quantities. This is done in innumerable cases in which the *plotting* of a quantity is effected and is the basis of the methods employed for obtaining continuous records of charging magnitudes. The important subject of graphical arithmetic and statics, curves of velocity, indicator diagrams, curves of bending moment, &c., as

well as working drawings for machinery and plans for building, all depend for their usefulness on the representation of magnitudes by lines of proportional length. In the widest application of plain scales we may say that the relations between material things are represented by relations between magnitudes in space, and they have in this way been of the utmost service in scientific discovery, presenting to the eye the general nature of the relation between two associated quantities, and suggesting to the mind the probable law of their connection in cases when the law is unknown.

A convenient form in which to use ordinary scales is to have a foot-rule divided into inches, and into the half, quarter, and eighth of an inch, like plotting scales, and then subdivided on the one side decimally and on the other side duodecimally, the edges of the rule being bevelled off so as to enable distances to be immediately pricked off from the scale on to the drawing. Frequently scales are required different from those which are usually made, and it is then necessary to make a scale of the required size on the drawing. This is also required when measurement has to be made on the drawing itself. The scale must then be put on the paper at the same time that the drawing is made, so that if the paper should alter its dimensions, the scale will alter in the same proportion. A valuable adjunct to a scale of this kind is a vernier scale, which enables us to take off small distances with far more accuracy than the ordinary diagonal scales.

Of the scales in the construction of which numbers found by calculation are used, the commonest are those found on the ordinary sector, which contains a scale of chords by means of which an angle may be more accurately set out than by the ordinary plain scale protractor. By it we are enabled also to set off lines proportional to the trigonometrical functions, to solve all questions in proportion, to reduce or enlarge drawings in a required ratio, to describe a polygon of a given number of sides, and to perform calculations by means of the logarithmic line. This last is a line numbered from 1 to 100, the distance from 1 to any number being made proportional to the logarithm of that number. Thus, since the logarithm of 10 is 1 and of 100 is 2, the scale consists of two parts, the part from 10 to 100 being a repetition of that from 1 to 10, since the logarithm of a number between 10 and 100, say 40, is equal to the logarithm of 10 added to the logarithm of the same number divided by 10, such as 4. Thus by the compasses alone we are able to perform, with a certain degree of accuracy, the operations of multiplication, division, finding a third or fourth proportional, and evolution and involution. For instance, to multiply 35 by 27 we should first multiply 3·5 by 27, or of 35 by 2·7, in order that the product might be less than 100, and afterwards multiply the result by 10. Taking in the compasses the distance on the scale from 1 to 3·5 we should set that interval beyond the 27 on the scale. We should then find the leg of the compass furthest from the beginning of the scale pointing to 94·5, so that the product required would be 945. A similar process obviously enables us to perform division. There is, however, some inconvenience in using the compasses, and this may be avoided by the use of the slide-rule. This rule consists of two parts, one fixed, which we shall call A, the other sliding, which we shall call B; on each of these parts a logarithmic line of numbers is placed. Hence by the sliding of the rule we can perform the same operations which would otherwise require the use of compasses. For instance, to divide x by y, place the number on B denoting y against the number on A denoting x, then the number on A which is opposite to the beginning of B will give the quotient required. Similarly the square root of a number may be extracted by so sliding B that the number on A opposite to 1 on B may be the same as the number on B which is opposite the number on A, the square root of which is required. The rule may be arranged in other ways so as to give at once the squares of numbers, the lengths of the spaces being made proportional to the logarithms of the squares of the numbers indicated. This is used, for instance, in finding the content of timber.

A slide-rule which has lately been devised by Major General Hannyngton, whilst remaining very compact in size, is capable of much greater accuracy. Here instead of one very long rule, the rule is divided into a number of parts which are placed under each other, each part being a continuation of the part above it; the slide also consists of a number of parts arranged under each other, consisting of a set of bars with spaces between, which are united at the extremities by cross pieces. The bars on the slide fit into grooves in the fixed part or stock, and are so arranged that the numbers on the stock and on the slide both begin together, although the former is longer than the latter, in order that in every position the slide may have a part of the stock opposite to it. The use of this "extended slide-rule" is the same as that of the ordinary rule, but in the case of the largest which is made, it is as exact as a rule ten feet long, whilst it is compactly arranged, so as to be only one foot long. By this rule all the operations performed by the ordinary slide-rule may be effected, but with much greater accuracy. On account of this it would seem as if this rule ought to become very popular when its merits become known.

The graduating of a scale so that the distances from the end of it may be proportional to the logarithms of the numbers which are marked on it, which is the principle of the slide-rule, is evidently capable of a greatly extended application, and different scales may be devised intended for different purposes. Thus a set of three scales has been devised by Mr. Lala Ganga Ram, intended for the use of engineers, architects, and builders. The first of these is intended to show at a glance the scantlings of timber in beams and joists, and to obtain the stresses in trusses. The principle employed is correct, and the results obtained are very approximate. The depth and breadth of a beam sufficient either for strength or stiffness, can be found by the same rule. It has on the reverse side a scale, by means of which the stresses in the principal rafter and the beam of a king post truss may be found, and then the same quantities may be determined for trusses of different form by multiplying by a certain coefficient marked on the edge of the scale. This gives without any difficulty the maximum stresses coming on the principal rafter and tie-beam, and is all that is usually required, since the scantlings or minor components of a truss are generally determined from practical rather than from theoretical considerations. The second scale is designed to give the thickness of retaining walls. By means of information contained on the back of it the thickness may be found for various forms of wall and kinds of loading. Here again the method of using the scales could not be simpler, and the results are such as agree with calculation. The third of the set enables us to find the stresses (or, as they are called by the inventor, in accordance with ancient custom, strains) on girders. When we state that this scale enables us to ascertain the stress on the flanges at any point of a beam up to 200 feet span, and also the shearing stress at any point of beams with different systems of bracing under both uniform and travelling loads, and that this is effected by merely sliding the scale, it is evident that we have here a means of obtaining at sight results which would otherwise require a considerable amount of calculation. The results are such as, for all practical purposes, seem to be abundantly accurate.

The principle of the slide-rule is thus one which is susceptible of almost indefinite application. It may be used in all cases when the results we wish to attain depend on calculations for which logarithms are ordinarily used

—in just those cases, in fact, in which calculation is laborious. It has the defect of logarithmic calculation in a very exaggerated degree, inasmuch as it is not accurate, but in very many cases this is of no great importance, since the degree of accuracy attainable is abundantly sufficient for all practical requirements. Scales possess one great advantage over methods of calculation, in that it is not possible to make the mistakes which so easily enter into arithmetical calculations. If they be accurately constructed, the modes of using them are so simple that there is scarcely a possibility of making a mistake, and we can predict beforehand the degree of accuracy which may be relied on. For engineering and other simple calculations we believe that these scales, and others like them, will be more and more used as they become more widely known.

THE FISHERY BOARD FOR SCOTLAND

THE second Annual Report of the Fishery Board for Scotland has just been issued, and contains much of scientific as well as economic interest.

The first Royal Commission on British Fisheries was founded in 1630. Immediately after the Union the fishing industry almost ceased to exist, owing apparently to the enactment of salt duties. In 1727 an Act was passed, by which the Board of Trustees for Manufactures and Fisheries was created, which, besides encouraging and superintending the fisheries, was empowered to pay certain "bounties" to the herring "busses," and offer premiums to the fishermen who first discovered herrings during each season at the different parts of the coast. In 1808 "An Act for the further encouragement and better regulation of the British White Herring Fishery" was passed. The Commission appointed to carry it into effect had charge of the whole fisheries of the British coasts, and later of the Isle of Man, and, in addition to granting bounties, had 3000*l.* placed at their disposal for encouraging the fishermen to use larger boats, so that they might go further out to sea. The Commissioners stationed officers at the chief coast fishing centres both in England and Scotland, and later two officers to the port of London, from whence large consignments of herring were sent abroad. The Admiralty provided a ship of war to assist in the work of superintending, and in 1815 a cutter was obtained for use in the Firth of Forth, and afterwards at other parts of the coast. Whatever influence the Commissioners had in improving the supply of fish and in developing the fisheries cannot now be estimated, but there can be no doubt that they rendered immense service in collecting statistics, which were till recently the only reliable fishery statistics extant, and of sufficient value to have justified the existence of the Board of Fisheries, even though all other work done were left out of consideration. From the statistics so collected, a valuable chart (Appendix A, Table VIII.) has been prepared by Mr. Robertson, one of the clerks of the Board, which shows at once the take of herring from 1809 to 1882; while Appendix C gives fresh statistics of the quantities and values of white fish and shell-fish. In 1820 the officers were instructed to take the cod and ling fishery under their charge; in 1821 the bounty for encouraging deep-sea fishing was withdrawn; in 1830 all bounties were repealed, and part of the money set aside for the erection of piers and harbours. In 1839 the Secretary of the Board of Manufactures was appointed Secretary of the Fishery Commissioners, and soon after this the Commissioners began to direct their attention to some of the hitherto neglected problems connected with the fisheries. In 1836 the question arose whether or not sprats were young herring, which Dr. Knox, who was appealed to, decided in the negative. This question having led the Commissioners to take an interest in the young herring, and to see the necessity of gaining some definite information as to the growth, food, and habits of the fish, Mr. Henry Goodsir carried on investigations in the Firth of Forth during 1843-44, from which it was ascertained that the food of the herring consists chiefly of young Crustacea. From the Report of 1846 it is evident that the Commissioners were acquainted with the fact that the herring ova sink and adhere to whatever they come in contact with. In 1850 the English stations were discontinued, and in 1856 another step in the right direction was taken, at the request of Dr. Buys Ballot, who invited those engaged in the great herring fishery to make observations in order to ascertain the circumstances likely to lead to the most profitable fishing and to enable them to make a herring chart. According to instructions issued by the Board of Trade, samples of herring collected on various parts of the coast of Scotland were forwarded to it, but no record is made of their examination. In 1860 complaints of the effects of trawling for white fish in the spawning grounds having led to another inquiry, Prof. Allmann decided that there was no evidence to show that trawling was likely to do injury to the spawning ground. No continuous investigations were, however, carried on by the Board, a new complaint being merely followed by a new inquiry or new Commission. Had the Board been provided with funds necessary to carry on continuous investigations as to growth, food, and habits of the herring and other useful fishes, much valuable information might have been obtained and great expense of Commissions of Inquiry avoided. It is therefore a matter of surprise and regret that, notwithstanding the example of other States, the influence of the Fisheries Exhibitions, and the demand for more information, the Treasury has not yet provided the new Board with sufficient funds. Another agitation arose in 1860, which led to the appointment of Prof. Allmann and Dr. Lyon Playfair, C.B., to inquire into the effects of trawling at the Fluke Hole, Pittenweem, and about the same time Dr. Playfair and Vice-Admiral Henry Dundas were requested to inquire into the claims of the sprat fishermen of the Firth of Forth. The agitation continuing, a Royal Commission, consisting of Dr. Lyon Playfair, C.B., Prof. Huxley, F.R.S., and Lieut.-Col. Francis Maxwell, was appointed in 1862 to inquire as to "the operation of the Acts relating to trawling for Herring on the Coasts of Scotland." The Report of this Commission is especially interesting, because it contains the results of the inquiries made by Prof. Allmann during the winter and spring of 1862 as to the nature of herring ova. The investigations made by him proved that the spawn of the herring "was deposited on the surface of stones, shingle, and gravel, on old shells and coarse sea-sand, and even on the shells of small living crabs and other Crustacea," and that it "adhered tenaciously to whatever matter it happened to be deposited on." The Report also contained a valuable chapter on the natural history of the herring, in which it is pointed out for the first time that there are two principal spawning periods, an autumn period with August and September as the two principal months, and a spring period with February and March as the principal months.

In 1873 the Scottish Meteorological Society began a series of inquiries with a view of determining how far the temperature of the sea and other meteorological conditions affect the migration of the herrings. From information obtained it was concluded (1) that the catch of herrings is less during any season with a high temperature than during a corresponding season with a low temperature; (2) that if the catch of herrings is higher in one district than in the other, the catch is greatest in the district with the lowest temperature; (3) that when the surface temperature is higher than the temperature lower down, the herrings seek the deeper water. It will be seen from the foregoing statement that the officers of the old Board were not utilised for making investigations. Important facts were however established as to (1) the

nature of the spawn; (2) the periods of spawning; (3) the food of the herring. In 1882 the Board of British White Herring Fishery having been dissolved, the present Fishery Board for Scotland was established, to carry on the work of superintending the fisheries, and also to "take such measures for their improvement as the funds under their ministration may admit of." The Board soon recognised the absolute necessity of obtaining accurate scientific information as to the habits and life-history of the food fishes, and therefore appointed a Committee consisting of Prof. Cossar Ewart (convener), Sir James R. Gibson Maitland, Sheriff Forbes Irvine, and J. Maxtone Graham, to carry on scientific investigations.

The preliminary report of work done in the autumn of 1883 and at Ballantrae has been already given in NATURE. The Admiralty has been pleased to provide a gunboat, H.M.S. *Jackal*, Lieut. Prichett, R.N., commander, to help in the investigations and inspect the spawning grounds, and the Board has also at its service the cruiser *Vigilant*, both of which vessels have done excellent work, though it is desirable that they should be replaced by others more capable of sea-going service. The Board is fortunate in having in its service a large staff of intelligent officers not only familiar with all the practical aspects of the fishing industry but deeply interested in the scientific work of the Board, which they aid to their utmost power. The future lines of inquiry which the Board hope to undertake include (1) the examination of the spawning beds round the Scottish coast; (2) the determination of the food of useful fishes; (3) the investigation of percentage of young herring, &c., destroyed by present modes of fishing; (4) the influence of sea-birds, &c., on supply of fishes; (5) study of spawning, nature of the eggs, and general life and development of herring, &c.; (6) best means of restocking deserted fishing grounds; (7) of increasing artificially the supply of shell-fish; and (8) of inquiry into fungi, &c., hurtful to fish life. The Board is fitting up a marine station at St. Andrew's, where Prof. McIntosh will make investigations for the Board, whilst similar work will be carried on in the Moray Firth. We trust that the impetus given to and the interest excited in the work of the Board may produce most favourable results, both economic and scientific.

We hope to return in a future number to some of the papers of specially scientific interest contained in this Report.

THE HISTORY OF A TYPHOON

PÈRE DECHEVRENS, the indefatigable head of the Meteorological and Magnetic Observatory at Zika-wei near Shanghai, has just published the first part of a work dealing with the typhoons of 1882. The present instalment is confined to those of the months of July and August in that year. The various plans and maps showing the course of the typhoons, and the height of the barometer at various times during their progress in different places, are so "fabulously complicated," to use the writer's phrase, that he fears more than one reader will regard his pamphlet as a work of imagination. Père Dechevrens, however, has had the advantage of observations made in China, Japan, and the Philippines by captains of vessels, lighthouse keepers, Customs officers, &c., such as have never before been made of any cyclone. Chinese typhoons, as he points out, fortunately for the meteorologist, though unfortunately for the navigator, ravage places visited by the ships of all nationalities, and hence with a little arrangement and organisation these phenomena may be easily studied in these regions. The Shanghai Chamber of Commerce and Sir Robert Hart have arranged for a regular supply to Père Dechevrens of a regular series of meteorological observations, and one of the earliest results is the pamphlet now before us. As a consequence of these wide and varied observations, the writer, while acknowledging the work of his predecessors, such as Spindler in Russia, Knipping in Japan, and Faura in Manila, claims that, while they were only able to give the history, as it were, of incidents in the life of a typhoon, he, thanks to the vast number and extent of the documents placed in his hands, has been able to connect these various fragments, and to trace the history of several typhoons from their cradle in equatorial maritime regions to their grave in the North Pacific Ocean. This, in his own words, is what Père Dechevrens has now done in his pamphlet. The first section deals with July 1882, and it is divided into several sub-sections, dealing with the formation of a typhoon on July 5, its progress in the China Sea, and a first separation or offshoot from the main storm, its progress on the mainland of China, the second typhoon of July 10 in the China Sea, and before Hong Kong, in the Formosa Channel, "its flight towards India, and its disappearance in the north of China," and finally an account of a typhoon in Hong Kong and Indo-China. The typhoons of August are discussed in a similar manner in detail, the conclusions being supported by observations made in all parts of the China seas and coasts. There are also a large number of diagrams. In his recapitulation the writer points out that, though he has been speaking of various typhoons, such as that in the Formosa Channel, in Hong Kong, &c., he has really been dealing with only one widespread storm, which, during its life of fifteen days, visited every coast from the equator to Siberia, and from the extreme east of Japan to the western frontier of India. The character which Père Dechevrens gives the phenomenon he has so carefully studied is this:—"It allows itself to stray with the greatest ease outside the straight path. In a truly headlong way it throws itself against all obstacles, gets into difficulties from which it can scarcely extricate itself, wastes its energies in whirlwinds, often powerless, which it abandons readily, goes, returns, hastens, stops still, in a word revolving always in the same circle, until, having expended all its strength, it disappears miserably at that part of the Pacific which in a short time would have been able to give it the necessary vigour to sustain a longer career, and, like many others, to reach the shores of North America, or at least, if retarded by the violence of the North Pacific, as far as Behring Straits." Three facts which this study renders prominent are:—

1. The extreme facility with which these typhoons divide and subdivide.
2. The mutual attraction and repulsion of atmospheric disturbances (whirlwinds).
3. The absence of the south-west monsoon in the Philippine Islands.

In his recapitulation these three points are discussed at some length in the summary, and we merely indicate them here to show the student what he may expect in this painstaking and learned publication.

HEALTHY SCHOOLS[1]

THERE can be no more appropriate product of an exhibition which seeks to illustrate the two problems of health and education than a handbook on healthy schools. Within the brief space of 72 pages Mr. Paget has brought together here some of the most important counsels which experience has suggested on structure, drainage, fitting, food, recreation, ventilation, and other conditions on which the health of children in schools depends. No school manager or teacher can read it without much profit; and the executive of the Exhibition has done the community a service by placing within its reach in a succinct and readable form so much practical knowledge and fruitful suggestion.

[1] "Healthy Schools." By Charles E. Paget, Medical Officer of Health for the Westmoreland Combined Sanitary District; Honorary Secretary of the Epidemiological Society of London. International Health Exhibition Handbook Series. (Clowes and Sons.)

Mr. Paget divides his handbook into two parts, the first relating to the right construction of schools, and the second to their right administration. Under the former head he discusses in succession the questions of the site, soil, and aspect best suited for the erection of schools; the due provision of light and of air, and the importance of a good supply of water both for drinking and for cleanliness. His estimate of the space required for each child appears to be excessive, and to be almost the only feature of his work which betokens a lack of practical experience, and a striving after an unattainable ideal. It is well known that the minimum space recognised by the Education Department under any conditions as sufficient is eight square feet of area, or eighty cubic feet of internal space for each child; but in schools built by Boards, or out of funds levied by rates, the Department insists on a larger provision, *i.e.* ten square feet of area and 120 cubic feet. Any one familiar with well-planned Board Schools of a modern type knows well that this space suffices to secure ample room for movement, for change of position for the arrangement and supervision of classes, and for a due supply of air. It will, therefore, be somewhat startling to school managers to learn that in Mr. Paget's opinion this provision is absurdly insufficient, and that 800 or even 1,000 cubic feet per scholar would not be too much. Perhaps it is wrong in such a connection to dwell on the question of expense. But when it is considered that the building of a good school, apart from the cost of the site, requires an expenditure of 10*l.* per head—a great London Board School for, say, 500 boys, 500 girls, and 600 infants, in three stories costing about 16,000*l.*—it will be easy to compute what would be the charge on the rates if each of the 1,600 children were to be furnished with an area of forty or fifty square feet in a room twenty feet high. The estimate is clearly enormous, and can certainly not have been founded on an observation of the actual dimensions of any school, whether elementary or secondary. Apart, however, from the consideration of expense, it may well be doubted whether such vast space would in any circumstances be needed. For the purposes of teaching and organisation a certain compactness of arrangement is clearly desirable, and the supervision of the head teacher becomes more difficult and less complete in proportion to the size of the area over which the work of the school is spread. These are considerations, however, which it would be right to overrule, if on sanitary grounds there were any necessity for such large spaces. But when the ordinary precautions which Mr. Paget suggests for insuring light cheerfulness and ventilation are taken, it is scarcely credible that any such necessity actually exists. Mr. Paget's estimate of the amount of cubic space needed in boarding schools, in cubicles, and dormitories, is not so large in proportion, and is indeed not wholly consistent with the demands he makes for space in a purely day school. Nevertheless, by placing it at 1,200 cubic feet per scholar, he practically condemns the arrangements in almost every boarding school in England; for the usual requirements are thought to be well fulfilled with exactly half that amount.

On the extent of the window-space, the provision of fresh air, the right construction and care of offices, the colouring of walls, the admission of light, the right attitude of the scholar, and the distance of his book in reading or writing, and the form of desks, the handbook abounds in judicious and definite suggestion. It is much less full and useful, however, in regard to the fitting of playgrounds, the organisation of games, and recreations generally. Teachers will be disappointed to find how little of practical guidance the book affords as to the best and healthiest forms of recreation, and the proportion which should exist between regulated gymnastics and the free spontaneous exercises which all boys and many girls can readily discover for themselves. On diet, bathing, sanatoria, and many details which specially concern boarding schools, Mr. Paget's advice is especially valuable and complete. His estimate of the time per day which may with full regard to all considerations of health be given to intellectual pursuits, will surprise some of his medical brethren who have been complaining of late of the ordinary school hours as excessive, and have been denouncing little home-tasks of half an hour long in the elder classes as a "burden too grievous to be borne." He computes that between the ages of seven and ten five hours a day is probably sufficient, and between the ages of ten and fifteen seven hours. When it is considered that even the elder and more diligent pupils in an elementary school are never under instruction more than five and a half hours a day for five days in the week, and that the hardest home-lessons ever given in such a school do not occupy nearly an hour a day; and when it is also considered that even in the girls' high school—in which the justest complaints have been made of excessive home-tasks lasting sometimes two hours—the actual attendance in the school itself is generally limited to four hours, it will be seen that the absurdly exaggerated modern outcry about over-strain receives no countenance from Mr. Paget. His own good sense and experience, in short, lead him to recognise the fact that after all the chief business of the boy's or girl's life is training and instruction; and that provided all needful precautions are taken for right distribution and variety of work, and for securing all the conditions of healthy and cheerful life, the hours usually devoted to education in England do not exceed a reasonable amount, but rather fall short of them.

It is not the least of the merits of the book that its suggestions are put forth modestly, and with a remarkable absence of dogmatism. When the writer is not quite sure of his ground he is careful to say that his remarks are tentative and suggestive only, intended to awaken interest in the subject rather than to exhaust it; and to lead the way to a fuller and more careful study of the whole theory of school hygiene with the aid of the numerous appliances now on view at the Exhibition. This reticence on points not yet finally settled tends greatly to increase the confidence of the reader in Mr. Paget's judgment on those topics on which he expresses a decided opinion.

NOTES FROM THE LEYDEN MUSEUM

It was a very happy thought of the late Prof. Schlegel to publish under the above title a quarterly record of the work done in the Royal Zoological Museum of the Netherlands at Leyden. The publication commenced in 1879, and the five yearly volumes before us, edited by Prof. Schlegel, will be one of the several enduring monuments to his memory. To all those interested in zoological research, the important treasures of the Leyden Museum are of necessity known. However indebted the Museum was to the well-known labours of Temminck, it is to the zeal and knowledge of Schlegel that it occupies its present high position among the museums of Europe. A very few words will show the importance from a zoological standpoint of these volumes, which contain on an average 250 pages each. The first volume contains descriptions of new species of mammals, birds, reptiles, insects, crustacea, and worms. These descriptions are for the most part by the director of the Museum and his Assistants, but help seems also welcomed from every hand, and the well-known names of R. B. Sharpe, P. Herbert Carpenter, Dr. D. Sharpe, Rev. H. S. Gorham, Prof. J. O. Westwood, occur among the British contributors. Besides containing numerous diagnoses of new species, these notes also from time to time present us with very important critical essays. Thus, in vol. i. Dr. A. A. W. Hubrecht's "Genera of European Nemerteans critically revised, with Descriptions of New Species," with a first appendix in vol. ii., is of great interest. It gives, so far

as European forms are concerned, a classification of the genera and details of the species found at Naples. With regard to a genus of De Blainville, Lobilabrum, which was founded on a single specimen of the species *L. ostrearum*, and which has never been again met with, the following instructive facts are recorded. This genus was easily distinguished from all others by the possession of a blunt snout with two horizontal lips at the extremity, both of them bilobed, and apparently with tentacles. The slit between the lips was described as being a continuation of the lateral fissures of both sides of the head. In other respects the genus bore a strong resemblance to species of Lineüs or Cerebratulus living in the same localities. One day at Naples Dr. Hubrecht was fortunate enough to come across a second specimen of this rare worm, which, like De Blainville's specimen, was dredged from a bottom covered with bivalve shells. It was duly figured and preserved, and longitudinal sections were made of its curious snout. Soon after he was struck by the extraordinary resemblance in habitat which existed between another Nemertean (whose anterior extremity exactly answered to that of a Lineüs or Cerebratulus, and carried two well-pronounced fissures), and this single specimen of Lobilabrum. Once the doubt was raised, Dr. Hubrecht pursued the investigation by purposely cutting off the tip of the snout in one of the last-mentioned species, in a direction vertical to the body axis. Immediately the curious arrangement of the lobed and tentaculated lips which had hitherto been limited to the genus Lobilabrum appeared, the animal operated on lived for several weeks, and afterwards longitudinal sections showed that an epidermal covering had made its appearance identical with what had been found in the Lobilabrum specimen. Considering these results with the fact of the habitat amongst bivalve shells, Dr. Hubrecht concluded that the genus of De Blainville had been founded on a specimen the tip of whose snout had been severed by an oyster into whose open shell it was stealthily trying to penetrate.

Amidst the many contributions to vol. ii. of especial importance is a memoir by G. C. J. Vosmaër, on the sponges belonging to the family of the Desmacidinæ; siliceous forms known by bow, anchor, and bihamate spicules with some criticisms on the works of Bowerbank and others. It is a well-known fact that the late Mr. Bowerbank did "not sufficiently understand the German language," and his remarks on Oscar Schmidt's important works in the preface in vol. iii. of the "Monograph of the British Spongidæ" were rendered still more negligent by the many typographical errors. Surely Vosmaër is wrong in the assertion that "only one man in England, Sir Wyville Thomson, has declared himself in favour of Schmidt's views" on classification, and we would venture to assert that of the classifications of the siliceous sponges invented by Bowerbank, Gray, or Carter, none have replaced that of Oscar Schmidt as recently modified. While promising to publish a more extensive memoir on the Desmacidinæ, with the indispensable illustrations of the new species, Vosmaër's present enumeration of the species is of very great value. As most of Bowerbank's type species are in existence, we trust that Vosmaër may consult these ere publishing his final memoir, as while we acknowledge as a fact that Dr. Bowerbank was a most accurate and painstaking observer, and a fairly good recorder of what he saw, experience has proved that he often, from one cause or another, overlooked even quite easily recognised characters. Vosmaër accepts 16 genera and enumerates 162 species. Of these he naively remarks:—"As the result of my study of them, plenty of synonyms have been described, but I have never felt the necessity of making two species from one!" F. E. Schulze has given many examples in his splendid studies on the Ceraospongiæ, especially in his "Die Familie der Spongidæ." Both Schmidt and Schulze have demonstrated that the word "species is to be used in a very wide sense" as regards the sponges. The scientific zoologist will hardly mind how wide, provided the definition thereof is such that, while it embraces all the forms it excludes none; and, despite their heteromorphism—their plasticness, so to say—the sponges are, as a result of good honest work, getting arranged into species and genera that may satisfy the most fastidious critic.

In the same volume of these "Notes" we find a paper by Prof. K. Martin, on a revision of the fossil Echini from the Tertiary strata of Java, which, working anew over the species described some thirty years ago by J. A. Herklots, quite reverses the conclusions of that author; and, instead of all or almost all of the species being different from existing forms, as insisted on by Herklots, Martin has succeeded in "demonstrating that by far the majority of all the well-preserved individuals could be identified with species still living in the Indian Ocean;" and he further mentions, citing the species found, and in addition the Mollusca, Crustacea, and Corals, that these Tertiary strata of Java contain no fossils which have also been found in extra-tropical Tertiary deposits, so that even in the Tertiary period the separation of the fauna of the tropical oceans appears to have been quite as distinct as we find it in the present day.

Vol. iii. contains a very charming account of the habits of the harvest mouse (*Mus minutus*) and of its winter nest, by Prof. Schlegel. It is written—as indeed are very many of the contributions to these "Notes"—in English, but the language of this little history is worthy of the author's name. There are also by Prof. Schlegel some interesting notes on the zoological researches in West Africa, which were carried on under his directions; and an important contribution to our knowledge of the Comatulæ in a memoir on the species to be found in the Leyden Museum, by P. Herbert Carpenter. The collection at Leyden is one of considerable importance, owing to its containing a large proportion of the types of the species described by Johannes Müller in his classical memoir, "Ueber die Gattung Comatula, Lamk., und ihre Arten." It is noteworthy that the whole of the Leyden collection of Comatulidæ were forwarded to Eton for study. For a possible trifling loss that a public museum may now and then sustain in a loan like this, there is sure to be an immense preponderance of gain.

A monograph of the African squirrels, with an enumeration of the specimens in the Leyden Museum by Dr. F. A. Jentink, commences vol. iv. While fairly and equitably reviewing the work on this group by Gray and Temminck he admits but two genera—Sciurus and Xerus, enumerating sixteen species of the former and three species of the latter genus. The synonymic lists appear to have been made out with the greatest care, of which care a very interesting example will be found in tracing the authority for the species *Xerus capensis* to Robert Kerr, who published his "Animal Kingdom, or Zoological System of the celebrated Sir Charles Linnæus" in 1792. Another contribution of Dr. Jentink which we find space to allude to is a revision of the Manidæ in the Museum. Seven species are described in detail. Under *Manis aurita*, Hodg., we read that it is still questionable whether a Manis occurs in Japan. Temminck mentions that Von Siebold sent over to the Leyden Museum two pieces of the skin of a manis from Japan, but as these fragments are not now to be found in the collection, it is of course impossible to say to what species they may have belonged. Mr. Serrurier, the director of the Ethnographical Museum at Leyden, informs Dr. Jentink that in the Japanese books at his disposal he finds nothing to justify the conclusion that the anteaters are inhabitants of Japan; but it would appear that the Japanese do introduce them for medical purposes from China. The Japanese also relate that the anteaters catch ants in the following way:—The manis erects its scales and feigns to be dead; the ants creep in between the erected scales, after which the anteater

again closes its scales and enters the water. He now again erects the scales, the ants are set floating, and are then swallowed by the anteater.

From a list of the Holothurians in the collection of the Leyden Museum, drawn up by Prof. Dr. Hubert Ludwig of Giessen, we find that the majority of the specimens in the Museum were incorrectly named, which is somewhat surprising; it seems also strange that of the species not so very long since described by Prof. Selenka the specimens are either *sine patria* or have the rather indefinite habitat of "Indian Ocean." The collection contains fifty-two species, two being new; most of them were obtained from the Oriental and Moluccan regions.

In vol. v. Dr. Jentink continues his very useful researches on the squirrels in the Museum. This time he treats of the American, European, and Asiatic squirrels; he acknowledges that the profound and extensive studies upon the American squirrels by Allen and Alston have made this group one of the best known among the Mammals; he enumerates ten species from America, forty from Europe and Asia. All the former are represented generally by numerous examples in the Museum, and of the latter only six species are among the desiderata.

The same volume contains "Notes of new species of the genus Megascolex, Templeton," by Dr. R. Horst. Very satisfactory evidence is given to show that Schmarda's genus Perichæta is but a synonym of Templeton's. Nine new species are described, chiefly from Sumatra, Java, and Japan; one, *M. musicus*, is described as living in the high mountain forests at Java, and is said to make a sharp interrupted noise during the night. The natives call it "tjatjing sondarie."

If in calling attention to these important contributions to our knowledge of the treasures of the Leyden Museum we have passed over the very numerous contributions to entomology, it is simply because our space forbids us referring to the immense number of new genera and species herein described; indeed these notes form a perfect magazine of entomology, and we feel sure are long ere this quite well known to all our entomological readers.

PRZEVALSKY'S WILD HORSE

GREAT interest is attached to the question of the origin of our domestic animals, and especially to that of the horse—which is generally supposed not now to exist in an aboriginally wild state. Every fact bearing upon this subject is of importance, and the discovery by the great Russian traveller, Przevalsky, of a new wild horse, more nearly allied to the domestic horse than any previously known species, is certainly well worthy of attention.

The horses, which constitute the genera *Equus* of Linnæus, and are the sole recent representatives of the family *Equidæ*, fall naturally into two sub-genera, as was first shown by Gray in 1825 (*Zool. Journ.* i. p. 241)—*Equus* and *Asinus*.

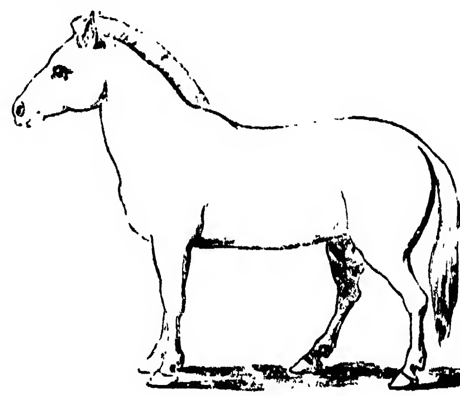
The typical horses (*Equus*) are distinguishable from the asses (*Asinus*) by the presence of warts upon the hind-legs as well as upon the fore-legs, by their broad rounded hoofs, and by their tails beginning to throw off long hairs from the base, instead of having these hairs confined, as a sort of pencil, to the extremity of the tail. Up to a recent period all the wild species of *Equus* known to science were referable to the second of these sections, that is, to the sub-genus *Asinus*, known from *Equus* by the absence of warts or callosities on the hind-legs, by the contracted hoofs, and by the long hairs of the tail being restricted to the extremity of that organ. Of this group the best known species, commonly called wild asses and zebras, are (1) the wild ass of Upper Nubia (*Equus tæniopus*), probably the origin of the domestic ass; (2) the wild ass of Persia and Kutch (*E. onager*); (3) the hemippe or wild ass of the Syrian Desert (*E. hemippus*); (4) the kiang or wild ass of Tibet (*E. hemionus*); (5) the quagga (*E. quagga*) of South Africa; (6) the Burchell's zebra (*E. burchelli*) of Southern and Eastern Africa; (7) the zebra (*E. zebra*) of Southern Africa. As already stated, these seven animals all possess the characters of the second sub-genus *Asinus* as above given, and no recent species of horse referable to the first sub-genus (*Equus*) was hitherto known to exist on the earth's surface, except the descendants of such as had been formerly in captivity.

Under the circumstances great interest was manifested when it was known that Przevalsky, on his return from his third great journey into Central Asia, had brought back with him to St. Petersburg an example of a new species of wild horse, which belonged, in some of its characters at least, to true *Equus*.

This new animal was described in 1881 in a Russian journal by Mr. J. S. Poliatow, and dedicated to its discoverer as *Equus przevalskii*.

The recently issued German translation of Przevalsky's third journey[1] enables us to give further particulars of this interesting discovery.

Przevalsky's wild horse has warts on its hind-legs as well as on its fore-legs, and has broad hoofs like the true horse. But the long hairs of the tail, instead of commencing at the base, do not begin until about half-way



Przevalsky's Wild Horse.

down the tail. In this respect *Equus przevalskii* is intermediate between the true horse and the asses. It also differs from typical *Equus* in having a short, erect mane, and in having no fore-lock, that is, no bunch of hairs in front of the mane falling down over the forehead. Nor has Przevalsky's horse any dorsal stripe, which, although by no means universal, is often found in the typical horses, and is almost always present in the asses. Its whole general colour is of a whitish gray, paler and whiter beneath, and reddish on the head. The legs are reddish to the knees, and thence blackish down to the hoofs. It is of small stature, but the legs are very thick and strong, and the head is large and heavy. The ears are smaller than those of the asses.

Przevalsky's wild horse inhabits the great Dsungarian Desert between the Altai and Tianschan Mountains, where it is called by the Tartars "Kertag," and by the Mongols "Statur." It is met with in troops of from five to fifteen individuals, led by an old stallion. Apparently the rest of these troops consist of mares, which all belong to the single stallion. They are lively animals, very shy, and with highly-developed organs of sight, hearing, and smelling.

They keep to the wildest parts of the desert, and are

[1] "Reisen in Tibet und am oberen Lauf des Gelben Flusses in den Jahren 1879 bis 1880," von N. von Prschewalski. Aus den Russischen frei in das Deutsche übertragen von Stein-Nordheim. (Jena, 1884.)

very hard to approach. They seem to prefer especially the saline districts, and to be able to do long without water.

The pursuit of this wild horse can only be carried on in winter, because the hunter must live in the waterless districts, and must depend upon a supply of water from melted snow. As may well be believed, such an expedition during the severest cold of winter into the most remote part of the desert, must take at least a month. During the whole time of his stay in the Dsungarian Desert, Przevalsky met with only two herds of this wild horse.

In vain he and his companions fired at these animals. With outstretched head and uplifted tail the stallion disappeared like lightning, with the rest of the herd after him. Prezevalsky and his companions could not keep near them, and soon lost their tracks. On the second occasion they came upon them from one side, yet one of the herd discovered their presence, and they were all gone in an instant.

The single specimen of Przevalsky's horse subsequently procured is now in the Museum of the Academy of Sciences of St. Petersburg, and is the only example of this species in Europe.

THE DIFFERENCE BETWEEN THE SEA AND CONTINENTAL CLIMATE WITH REGARD TO VEGETATION

THE difference in vegetation between the sea and continental climate is no doubt best observed in the growth of plants generally cultivated in the temperate zone for different purposes, as every climate has its own region or flora. Whether the climate of a country is favourable to those plants or not is shown, in the first place, by their extension to the north; therefore we shall first endeavour to trace the northern limits of the most important plants, either cultivated in one country and growing wild in another, or cultivated everywhere.

To the first class trees mostly belong; to the second, annual or perennial plants. We begin with trees:—

Pinus sylvestris, L. (Scotch pine). Scotland, 59°; Norway, 70° 20′; Kola, 69°; Petchora region, 67° 15′; Ob River, 66°; Turukansk, 65°. The Verkhoyansk Mountains, east of the Lena River (64°), are the eastern limits of this tree.[1]

Betula odorata, Bechst. (*alba*, L., var.) (birch). Greenland, 61° (shrub); Iceland, 65° (shrub to ten feet high); Britain, 59°; Norway, 70° 50′; Kola Peninsula, 69° 30′; Kanin Peninsula, 67°; to the Ob River (66°), and from the River Kolyma (68°) to the Penshina Gulf (63°) and Kamchatka; on this peninsula it is a large tree.

Quercus pedunculata, Ehrh. (*Q. robur*, L., var.) (common oak). England, 58°; Norway (wild), to 62° 55′, and cultivated to 65° 54′; Finland (coast), 61° 30′ (Bjorneborg); St. Petersburg, Yaroslav, Perm, 58°.[2]

Larix europæa, Dec. (including *L. sibirica*. Ledeb., and *L. dahurica*, Turcz) (common larch). Norway (*europæa*, Dec.), 66° 5′, (*dahurica*, Turcz), 59° 55′, both cultivated; Onega River, White Sea, south-western shore of Onega Lake, Mesen (Kanin Peninsula), 67°; Petchora River, 67° 30′; Ural Mountains, 67° 15′; Kara River, 68° (northern limit in Europe); Yenisei River, 70°; Boganida River, 71° 15′; Chatanga River, 72° 30′ (most northern limit of trees on the globe); Anabar, 71°; Olenek and Lena, 72°; Yana, 71°; Indigirka, 70° 45′; Kolyma, 69°; Anadyr, 65°; between Okotsk and Gishiga, 61°; Sakalin Peninsula, 49°; to Jeddo and the island of Kunaschir, 43° 45′. On the shores of Kamchatka the larch is nowhere to be found; in the valleys of this peninsula, however, protected from sea winds, it is a very large tree.[3]

[1] Middendorff, "Sibirische Reise," Bd. iv. Th. 1, p. 556.
[2] *Ib.* p. 567.
[3] *Ib.* p. 536.

Pyrus Malus, L. (apple-tree). Shetland Isles (cultivated); Britain, 57°; Norway, cultivated, 65° 28′, wild, 63° 40′; Gulf of Bothnia, 63° 45′ (cultivated); Finland, 63° (cultivated), 60° (wild); northern shore of Onega Lake (wild); Narva, 59° 30′ (wild); Tver, 56° 45′ (wild); Nijni Novgorod, 56° (wild); Kasan, 56° (wild); south-west of Orenburg, 50°; Kopal, Asia, 45°.

Fagus sylvatica, L. (common beech). Britain, 58°; Norway, 59°, cultivated, 67° 56′; Sweden, 57°; Königsberg, Poland, South-West Russia, Crimea, Caucasus, Persia.

Castanea vesca, Grtn. (chestnut). South Britain, Germany (to the island of Rügen), Austria, Caucasus.

Populus alba, L. (abele tree). Britain (wild and cultivated), 56°; Norway (cultivated), 67° 56′; Germany (wild and cultivated), Austria, Russia: Volhynia, Kieff, Charkoff, Tambov, Kasan, Ufa, Altai Mountains.

Populus tremula, L. (aspen). Britain, 59°; Norway, 70° 37′; Russia: Kola Peninsula, 69° 30′; eastern shores of the White Sea, 66°; Yenisei, 66°; Kolyma River, 67° 30′;[1] Amur River.

Alnus incana, W. (hoary-leaved elder). Canada, Norway, 70° 30′; Kola, 69° 30′; Yenisei, 67°; Amur region, Petropaulovsk on Kamchatka.

Ulmus campestris, L. (common elm-tree). Britain, 57°; Norway (cultivated), 63° 26′; Russia: Ilmen Lake, south of Moscow, Riazan, south of Kazan and Ufa to the Ural Mountains.

Tilia europæa, L. (including *parvifolia*, *grandifolia*, and *intermedia*) (lime-tree). Britain, 57° (*parvifolia*); Norway (wild), 62° 9′, (cultivated) 67° 56′; St. Petersburg, Kargopol, Ust Süssolsk, about 62°; Solikamsk, Ural Mountains, about 58° 50′; Verkhoturgi.

Vitis vinifera, L. (common grape). Bretagne, 47° 30′; Liége, 50° 45′; Thuringia to Silesia, 51° 55′; South Galicia, South Russia, between about 48° and 49°; Astrakan, Bokhara in Turkestan, 40° (here the vine is cultivated in the open fields[2]); Khiva, 42°; China, 40°; California. This plant cannot stand the extreme continental climate on account of the frost in winter, but wants a very warm or a very long summer (as in California), therefore it cannot be cultivated generally in Britain. California is warmer in summer than some latitudes in Europe.

Triticum vulgare, Vill., var. *æstivum* (summer wheat). Britain; Norway, in the fields, 64° 40′, in gardens, 69° 28′; Finland, 65°;[3] Dwina River, 63°; Yakutsk, western shores of North America, 55°; Fort Liard, 60° 5′ (North-West Territory of Canada);[4] Peace River, 56° 6′; Ontario, East Canada.

Hordeum vulgare, L. (including *hexastichum*) (barley). Faroe Isles, 62° 15′ (grain seldom ripens); Norway, 70°; western shores of the White Sea, 67°; Ob River, 61°; Yakutsk, 62°; Udskoi Ostrog, near the Okotsk Sea, 54° 30′; Kamchatka (inland), 53° to 54°; North-West American shore, south of Sitka, 57°; Fort Norman, Mackenzie River, 65°;[5] east of Winnipeg, 50°; St. Lawrence Bay, 50°.

Avena sativa, L. (oat). Scotland; Norway, 69° 28′; Finland, 69°; Asia, the same latitude as *Hordeum vulgare*; Yenisei, 61°; Yakutsk, Kamchatka (inland); North America, the same latitude as *Hordeum vulgare*.

Secale cereale, L. (common rye). Britain; Norway, 69° 30′; Finland, 67°; Mesen River, 65° 45′; Petchora region, 65° 45′; Ural Mountains, 57°; Ob River, 60°; Yenisei, 59° 30′; Yakutsk, Kamchatka (inland); North America, a little south of the latitude of the barley, eastern shores, 50°.

Solanum tuberosum, L. (potato). Britain; Norway, 71° 7′; Russia, Pinega River, 65°; Turukansk, 65°; Yakutsk, shores of the Okotsk Sea, Kamchatka, Kadjah Island,

Sitka Island; Mackenzie River, 65°; Canada; Labrador, 58° 45'; [1] Greenland.

Zea mays, L. (Indian corn). This plant requires also a very warm summer to ripen its seeds. In England it can only be cultivated as a green vegetable; on the western shores of Europe we can say that the cultivation is only profitable to the 46th degree N. lat., and in the valley of the Rhine it reaches to 49°. In North Germany the grain usually does not ripen. In North America, however, it is cultivated in certain regions with profitable returns up to 51° N. lat.[2] The period of vegetation varies there between seven and three months. To cultivate the varieties of such a short period in Europe is tried, but without result; they were transformed after a few generations into the common corn.

Thus we see that, of the plants just named, the larch, the pine, the birch, and the aspen grow in Siberia, with its excessive continental climate, farthest to the north; yet many of the cultivated plants mentioned above, and almost all those of the temperate zone, are either cultivated or grow wild in the sea climate of Norway, to very high latitudes.

On the north-western shores of America the pine attains a considerable size (island of Sitka), in a climate with continual rain, but partly the same size is observed on the Rocky Mountains (eastern slope), where the climate is wholly changed.

In British Columbia the climate is continental, very cold in winter; yet the same gigantic trees as on the coast are to be found here; precipitation takes place in spring, but the amount is very great.

In California, with its largest coniferous trees of the world (*Wellingtonia gigantea*), rain falls chiefly in winter (November to April). The enormous differences of coast and inland climates of California are not apparently known.

In the southern parts of the Amur region in Asia there is in summer a luxuriant vegetation; the annual precipitation amounts to 27·56 inches (about the same amount as in Germany), the plants much resembling those of Central Europe,[3] and this notwithstanding a winter temperature much lower than observed in the most northern parts of Lapland; but the summer here is much warmer than in Europe under the same latitude, and precipitation *occurs only in summer*.

In the interior of Siberia the vegetation consists chiefly of coniferous trees; thus the luxurious growth in the region just named must be caused by the influence of the sea climate, as Middendorff suggests,[4] though there is a mountain chain on the east coast. The extensive forests of Russia and Siberia prove that an extreme continental climate is resisted by some coniferous and other trees, but it is evident that in general a sea climate with mild winters, and thus a long period of vegetation, suits them best.

As we have seen, the northern limit of the cultivation of corn reaches on the continent a much higher latitude than on the shores. On the north-west coast of North America the island of Sitka (57° N. lat.) and Kadjak are on the extreme limit. On the Färoe Isles, barley (this can only be the coarse variety) is cultivated, but the grain very seldom ripens;[5] the cause is absence of sunlight on account of the continual cloudy sky, storms and precipitation, causing low temperature in summer (mean temperature at Thorshaven, July, 49°·8), for corn wants a sunny climate, and to be under the direct influence of the sun's rays. This explains why it can be cultivated within the Polar Circle (Norway), where the sun in the summer season remains constantly above the horizon.

In North America, on the shores of Hudson's Bay, the tree limit goes down to 59°, the corn limit to 50° (Ontario).

On the shores of the Okotsk Sea corn cannot be cultivated at all, even on the south coast, under 50° N. lat. In Greenland the culture of corn is also impossible. The causes are the same as said above: the sea winds, wet climate, and fog in summer—thus want of sunlight.

Of all the cultivated vegetables, *Raphanus sativus*, L., et var. (radish), *Brassica rapa*, L., et var. (turnip), and *Brassica Napus*, L., et var. (rape), grow as far north as there are settlements—in Norway beyond 70° N. lat.; in Siberia to the Polar Circle; on the north-west coast of America to 64° 45' (Nulato), and Redoute St. Michael, 63° 30', in the interior to 67° (Fort Good Hope).[1] In Greenland rapes, turnips, cabbage, and salad are cultivated under 70° N. lat. (Island Disko).

The potato follows the above-named plants in their distribution to the north, and belongs also to the sea climate; at its northern limit in Siberia, however, as well as in North America, it is the size of a walnut.[2] In Greenland only the most careful treatment can produce eatable ones. The plant never blossoms here.[3]

When comparing the vegetation of the extreme continental climate with that of the extreme sea climate on the globe, the continental has the advantage; the South Shetland Isles, in 60°-63 S. lat., are at the most southern limit of phanerogamous plants (only a grass, *Aira antarctica*, Forst., is found here), and on Cockburn Island (64° S. lat.) the last trace of vegetation is found (cryptogamous plants). At this latitude north there is in Siberia a forest of very high coniferous trees. In the Antarctic regions there are several causes why vegetation ceases at such a low latitude, but these are all consequences of the chief cause, viz. the fact that the whole southern hemisphere, with the exception of relatively small spaces, is covered with water; severe storms[4] combined with a very low summer temperature[5] banish all vegetation.

The extreme continental climate has also its disadvantages, but chiefly with relation to the cultivation of corn. In the first place corn is very often destroyed by night frosts; they make the harvest uncertain.

The constantly frozen ground is the chief cause why corn cannot be cultivated in Siberia beyond 62° (Yakutsk). The temperature of the soil in which the roots vegetate varies between 36° and 41°. Thus notwithstanding the mean temperature of June at Yakutsk being 57° and that of July 62°,[6] the vegetation is relatively slow, though its period is the same as observed in Central Europe (ten to twelve weeks).[7] The same period is observed in North America, at 63° (Fort Simpson), of the barley (wheat does not come to maturity here). But harvests of thirty to forty times the amount of what was sown alternate in this climate with years of no harvest at all.[8] It is known that the native plants withstand the lowest temperatures of the Siberian winter.

Returning to Europe, we have seen that even the climate of the northern parts of the British Isles is not suited for many vegetables and other cultivated plants. It is Germany which has a climate where we can find almost all the plants of the temperate zone and those commonly cultivated; we see the vine in this country ascend farthest to the north, while corn and all vegetables ripen their seeds perfectly. It is clear that the climate is best suited for the vegetation of this latitude.

Now if we compare the mean temperature of July in Germany with the mean for the latitude (for 50° N. lat. 62°) calculated by Dove, we find that even in this country

[5] In lat. 64° 5' mean temperature of January 1843, 31°; in 62°-66° in February, 31° (see Ross, "Voyage in the Southern and Antarctic Regions," vol. ii. pp. 352, 360.
[6] Middendorff, p. 772. [7] *Ib.* p. 718. [8] *Ib.* p. 720.

the summer temperature in general is only *a few degrees above the calculated;* Germany is crossed in July by the isotherm of 68°, and Britain by that of 59°; but the difference in vegetation is not caused by a difference in mean temperature of 9°, but by the difference in the *amount of sunshine.*

Thus we come to the conclusion that a mixed climate, with relatively mild winters (the anomaly of temperature for January is for Germany about 19° on the 50th parallel of latitude) and *warm sunny* summers, is the best suited for the vegetation of the temperate zone.

Flushing M. BERGSMAN

NOTES

THE International Congress of Hygiene will sit at the Hague from to-day till the 27th inst. Papers will be read by Messrs. Pasteur of Paris, Finkelberg of Bonn, Stephen Smith of New York, Marcy of Paris, W. H. Corfield of London, Emile Tiélat of Paris, J. Crocq of Brussels, and A. Corradi of Pavia.

THE International Medical Congress at Copenhagen has been a great success. The next meeting will be held at Washington in September 1887. On behalf of the Collective Investigation Committee of the British Medical Association, Sir William Gull delivered an interesting lecture on the International Collective Investigation of Disease. A resolution for the establishment of a Permanent International Committee for the Collective Investigation of Disease was received with acclamation.

IN an interesting descriptive article in the *Times* of yesterday on the Health Exhibition Biological Laboratory, the writer makes some forcible remarks on the position of research in this country. "Just as the advantages of such an institution as the projected Marine Biological Laboratory were illustrated and brought home to the mind by the International Fisheries Exhibition of 1883, so the present Health Exhibition should, as one outcome of its usefulness, lead to the foundation of some such institution for the extended and systematic study of the minute organisms which there is reason to believe are the causes of many forms of disease in plants, in animals, and in man. In Germany the State, recognising the value of the labours of Dr. Koch, contributes, though not very largely, to the prosecution of researches which give promise of invaluable results to all mankind. France, too, has acknowledged the practical character of the benefits which have in some measure already resulted from the experiments of M. Pasteur. In this country, where the State endowment of research is hardly admitted in principle, and where we have, perhaps too long, been content to leave all scientific research which was not directly remunerative to be pursued, with few attempts at organisation, by the few private individuals who, having the means, care to devote time and money to such objects, students of biological science are wondering whether the Royal College of Surgeons will apply some portion of the splendid bequest of Sir Erasmus Wilson to the purposes of research in this comparatively little-known but interesting field of inquiry. Without entering upon debatable ground, it may be said that in the small model laboratory for biological research, fitted up under the direction and now under the charge of Mr. Watson Cheyne at the Health Exhibition, the public may see and learn enough to convince the most sceptical of the vital importance of the knowledge which it is the purpose of such observations and experiments as are there exemplified to obtain."

PROF. G. F. ARMSTRONG, of the Yorkshire College, Leeds, and formerly of Montreal University, writes to the *Times* of Monday last, drawing attention to the liberal provision made for technical education in America. The Americans, he maintains, are a generation ahead of us in this respect. At the same time he draws attention to the danger of neglecting the preliminary general culture which is absolutely necessary as a sound foundation for any special training.

IT is worthy of note that the Roman Catholic Church of St. John, built by the Marquis of Bute, at Old Cumnock, Ayrshire, has recently been fitted throughout with the electric light under the personal superintendence of Mr. William Massey, of Twyford. There are in all about seventy glow lamps of twenty candles each, and the effect is very perfect, the architectural features of the building having been carefully studied and the lamps arranged with due regard to the religious character of the place. The necessary current is supplied by means of a dynamo and steam-engine placed in a small house hidden among the trees of the churchyard, where it is also intended to generate electricity for working the organ bellows.

THE inauguration of the Jouffroy statue at Besançon took place on Aug. 17. According to the French notion the Marquis de Jouffroy is believed to have been the real inventor of steam navigation, and the precursor of Fulton. M. de Lesseps was present at the ceremony.

THE effect of cheap interior telegraphy has been felt most happily in France, where the number of telegrams has multiplied in the most extraordinary manner. Last year there were 58 telegrams for each 100 inhabitants.

A FRENCH surveying vessel, the *Henri Rivière*, so called after the great explorer who lost his life in Tonquin, is to be sent to the higher waters of the Songkoi or Red River, not only to keep order among the pirates there, but also to survey the districts adjoining, and correct the inexactness of existing maps of the course of the river. As the ancient Khmer kingdom, Cambodia, has now been practically annexed to France, we may soon expect that the centre and eastern coast of the Indo-Chinese peninsula will be as well known to us as British India now is, for the French spare no money or pains to study their colonial possessions thoroughly.

AT the last meeting of the Paris Academy of Sciences, M. F. A. Forel described some peculiar luminous phenomena frequently observed by him and others during the spring and summer of this year at Morges on the Lake of Geneva, and especially on the Alps. When the sun was half veiled in white vapours, the clouds at Morges presented a reddish appearance at a distance of 20° or 25° from the solar disk. But the light effects were far more vivid when seen in the pure atmosphere of the Alpine regions; and in clear weather, that is to say, almost every day during the last fortnight, they were distinctly observed in the upland valley of Saas-Fée, Canton of Valais. The sun appeared as if encircled by a silvery white halo, very bright and lustrous, somewhat similar in appearance to the weird glow noted in the first phase of the crepuscular displays so frequently observed during last winter. This halo, whose radius may perhaps have measured some 12°, was itself surrounded by a broad, reddish corona with badly defined limits, whose orange or violet tints blended on the inner side with the silver halo, and outwardly with the azure sky. In breadth this corona was about equal to the radius of the halo. For a considerable distance from the sun the sky beyond these effects was of a deeper blue than usual, as was evident especially in the evening, when the setting sun disappearing behind the snowy Alpine crests seemed to impart to the western regions the shifting hues of a stormy sky. One might fancy the sun visited by a great dust-cloud, but for the fact that, beyond these displays of colour, it was as luminous as ever, the firmament itself as serene, with deep azure tints, the transparency of which nothing seemed to impair. The phenomenon attained its greatest intensity on July 23, a lovely midsummer day, when it was also observed at Sand-Alp in the

Canton of Glaris, at Kandersteg in the Canton of Berne, and at Charmey in the lower Valais. On the same day M. Auguste Arcimis noted crepuscular glows at Madrid analogous to those of last winter. He remarked in particular a bright corona around the sun, of a silvery white and with a diameter of about 48°. On the Alps the display remained more or less visible every day; but since his return to the plains on August 8, M. Forel lost all traces of it. He was assured by several observers that the phenomenon had been constantly noticed in Valais during the spring and summer of the present year. M. Forel asks whether it is to be regarded as a sequel to the surprising series of optical effects successively observed in the various regions of the globe since the tremendous eruption of Krakatoa on August 27, 1883, effects which in Europe reached their culminating point in the crepuscular glows and auroral displays of last November, December, and January. In connection with the same subject M. Jamin remarked that similar phenomena have been observed at Paris and in various parts of France during the exceptional heats of the last few weeks.

Lieutenant Greely has published further details respecting his three years' residence in the Arctic regions. He says the extremes of temperature at the camp on Discovery Bay, which they had named Fort Conger, was from 52° above freezing-point t. 66° below. In February 1883 the mercury was frozen into a solid mass, and continued in that state for fifteen days. The ordinary outdoor clothing of heavy flannels was found to be quite sufficient even on the coldest days. The extreme range of the barometer was from 29 in. to 31 in. The electrometer registered nothing. The aurora was noiseless, which is contrary to Sir George Nares's experience in 1876, but it was sufficiently bright to cast a shadow. The tide at their most northern settlement flowed from the north; that at Cape Sabine came from the south. The northern tide was two degrees warmer than that from the south. In Lady Franklin Bay it rose eight feet, and the Cape Sabine tide twelve feet. Surf was seen twice. The temperature of the water at the earlier camp averaged three degrees below freezing-point. During two years only two small sea fish were caught; but in Lake Alexander fine salmon were taken. Between Capes Bryant and Britannia Lieut. Lockwood found no bottom with a line of 155 fathoms. At the furthest point north which Lieut. Lockwood reached there was no Polar current, nor did he discover any open sea. The only sea animals met with were the walrus and different species of seal. The vegetation was similar to that seen all over the extreme north. At Lady Franklin Bay the deflection of the magnetic needle was 104 west. The coast of Greenland trended in a north-easterly direction as far as it could be traced. Lieut. Greely thinks the Pole will never be reached, unless every condition which has hitherto been unfavourable should be simultaneously favourable. The only route at all likely to prove successful is, he thinks, by Franz Josef Land. The Polar pack generally, which was reported by Dr. Pavy and Lieut. Lockwood to have been seen by them, almost certainly, Greely considers, proves the existence of an open Polar sea. No hardship was experienced by the explorers while they remained at Fort Conger; and if their physical condition had not degenerated the survivors believe they could have remained there ten years.

Under the title of "Bosquejos Ethnologicos," S. Carlos von Koseritz has just published in collective form a series of papers contributed by him during the last three years to the *Gazeta de Porto Alegre* on anthropological subjects in the province of Rio Grande do Sul and other parts of Brazil. A chief object of these papers is to place on permanent record the general conclusions based on a comparative study of the extensive ethnological collection to the formation of which the writer had devoted fifteen years' patient labour, but which was unfortunately completely destroyed in the disastrous fire at the Brazilian German Exhibition of Porto Alegre last year. The collection comprised over 2000 objects of all sorts, but chiefly rude and polished stone implements brought together from various parts of Rio Grande, and generally corresponding to those of the stone epochs in Europe. But those of a strictly Palæolithic type appear to be very rare, and as they occur promiscuously with Neolithic objects, the author infers that it is impossible to determine a Palæolithic antecedent to a Neolithic age in Brazil. A few rudely wrought diorite or nephrite weapons occur, as well as some quartz arrowheads fashioned with great labour. But the great majority of the arms and utensils are of more or less polished diorite. Many were found associated with the remains of the Megatherium, of the *Rhinoceros tichorrhinus*, and the cave bear, thus confirming the conclusions already deduced from the discovery of the fossil man of Lagôa Santa in Minas Geraes, and arguing as great an antiquity for the *homo Americanus* as for the River Drift men of the Old World. At the same time the writer considers that the earliest inhabitants of South Brazil were quite distinct from, and of a much lower type than, the Charruas and other tribes in possession of that region during the historic period. This conclusion is based especially on the evidence afforded by the skeleton recently found in a shell-mound on the banks of a fresh-water lagoon near Cidreira, within three miles of the present coast of Rio Grande. During its removal to Porto Alegre, this skeleton, which must have been many thousand years old, got broken, but the skull has been carefully restored by Theodore Bischoff, and presents the same remarkable characteristics as two others of uncertain origin preserved in the National Museum of Porto Alegre. It is even of a more decidedly bestial type, with excessive prognathism of the upper jaw, extremely long and high cranium (hypsistenocephaly), depressed brow, prominent superciliary arches, imparting altogether a most ferocious expression to this specimen, which from the worn state of the teeth seems to have belonged to a very old man. Altogether the Cidreira skull completely confirms the views of Lacerda regarding the prehistoric race associated with the shell-mounds of South Brazil, a race which appears to be at present best represented, at least in some of its salient features, by the fierce Botocudos of the Aimores Mountains further north. It seems to have come originally from those highlands, and the author thinks it probable that the men of the Santa Catharina and Rio Grande refuse-heaps all belonged to the same aboriginal stock.

The glaciers of the province of Terek, in the Caucasus, are the subject of a vivid description by M. Dinnik, in the last number of the *Mémoirs* of the Caucasian Geographical Society (vol. xiii.) With the exception of the Adyl glacier, all those visited by M. Dinnik have been rapidly decreasing during this century. The great glacier of Bizinghi, one of the largest in the Caucasus (it is nine miles long, and one mile wide about the middle), has two great terminal moraines, one mile below its present end, and several lateral moraines, some 500 yards distant from its present borders, some of which still conceal masses of ice under the boulders and mud. On its western border an old moraine rises at least 200 feet above its surface. The same is true with regard to the great Azaou glacier of the Elbrus. Even the inhabitants have witnessed the retreat of glaciers, and they remember the time when the Bizinghi and Mijirghi glaciers, now one mile distant from one another, were connected together at their ends. Besides these relatively recent moraines, there are around the glaciers several others the boulders of which are much more worn out and more rounded, which testify to a former still greater extension of glaciers. As to the Adyl glacier, it was also decreasing when a formidable mass of mountain above it fell into the valley some eighteen years ago. It was broken to pieces, and its debris thickly covered the glacier for some five miles. The debris, which have still at

many places a thickness of several yards, have protected the ice from melting, and have made it advance down the valley.

THE last number of the *Memoirs* of the Caucasian Geographical Society (vol. xiii. part 1) contains a series of very interesting papers. M. Dinnik contributes three papers, in which he describes his wanderings through "the mountains and gorges" of the provinces of Terek and Kuban in Ossetia and about the sources of the Rion. The author devoted his attention especially to the glaciers of the tracts he visited, but his descriptions give a very striking picture of the general characters of the region, of its flora, and especially of its fauna. His remarks on this last will be most welcome to the zoologist and geographer. M. Weidenbaum gives an historical sketch of the different ascents of Ararat, and of the scientific conquest of its summit, so boldly denied each time by the Armenians, who do not admit that human feet may step on the virgin snow of the holy summit. The ascents of Tournefor, Parrot, Abich, Khodzko, Messrs. Freshfield and Tucker, and Bryce are described by the author. M. Lessar contributes a paper on his journeys to South Turcomania, Merv, Chardjui, and Khiva (already known from what has appeared in the St. Petersburg *Izvestia*). M. Kossikov gives a narrative of his journeys to the Upper Daghestan and Chechnia, and describes also two villages, Konhidatl and Enheli, situated in the gorge of the Andian Koyson, the inhabitants of which are engaged in salt-mining. Two lithographs give an excellent idea of this crow's nest in the mountains, the flat-roofed houses of which are built upon one another, offering at the same time a means of defence and an economy of the poorly-allotted space on the slopes of stony crags.

IN a former paper to the Russian Chemical Society, Prof. Mendeléeff had arrived at the conclusion that the dilatation of liquids can be expressed by the formula $V = \frac{1}{1 - kt}$, where k is a module which varies for different liquids, and increases with their volatility. The researches of M. Van der Vaals, combined with the above, have enabled Messrs. Thorpe and Rücker, in the April number of the *Journal* of the London Chemical Society, to establish the remarkable relation between the absolute temperature of boiling t_1, reckoned from the absolute zero ($-273°$), the volume V_t measured at a temperature t, and a constant a, which seems to be near to 1·995 or 2. Now, in a communication to the Russian Chemical Society (vol. xvi. fasc. 5), Prof. Mendeléeff shows that, if the dilatation of gases and that of liquids be expressed by the formulæ—

$$V_t = 1 + at \text{ and } V_t = \frac{1}{1 - kt},$$

which would give $2t_1 = \frac{1}{k} - \frac{1}{a}$, and the constant a be taken equal to 2, we receive—

$$\frac{1}{k} = 2t_1 + 273,$$

where k and t_1 are determining one another. This deduction is confirmed, in fact, by direct measurements. The further progress in the mechanics of liquids, he says, must be expected from new experimental and theoretical researches into the compressibility of liquids at different temperatures and into its relations to the modulus of dilatation; the fundamental equation of liquids must express the relations between their volume, temperature, and pressure, as is the case for gases. As to a complete conception of the ideal state of bodies, it must contain also the relations to their molecular weight and composition.

THE "Handbook of the St. Nicholas Agassiz Association," issued by the President, Mr. Haslan H. Ballard of Lenox, Mass., is a little work of great interest, and should also be of much utility to those who desire to train up the young with a love for Nature, and a desire to study her products and ways. The Association had a very modest beginning. Mr. Ballard was teaching in a school in Lenox, and in 1875 got his pupils to band together for the observation and study of natural objects. "It was the outgrowth of a life-long love for Nature, and a belief that education is incomplete unless it include some practical knowledge of the common objects that surround us." The idea was actually derived from a similar association in Switzerland, took root and flourished in Lenox, and after a few years the President thought that it might be extended to other places. The assistance of the editors of the well-known *St. Nicholas* magazine for the young was then invoked, and in 1880 a general invitation to others to join in the work appeared in that periodical. The response was very gratifying. Classes have been formed in various towns under the direction of the central organisation, and now 650 local scientific societies are at work with over 7000 students. Nor is it confined to the youth of both sexes, although originally intended for them, for the parents in many instances join, and there are some "chapters," or classes, wholly composed of adults. Still the work is principally among the young, and Mr. Ballard notes that the Association has found a wide field of usefulness in connection with public and private schools. Many teachers, he says, who have not been able to find a place for natural science in the ordinary school curriculum, and who have yet felt that their pupils should not grow up strangers to the flowers, trees, birds, and butterflies, have been glad to devote an hour once a fortnight to the guidance of a meeting devoted to these studies. The "Handbook," after describing somewhat enthusiastically and picturesquely the advantages of the Association, proceeds to give directions as to the formation and conduct of a class. Then follow chapters on the plan of work, how to make a cabinet, to collect specimens, what to do in winter and in the city, and so on—in fact, directions for the young student in every department of natural history to which he could turn his attention. A list of books recommended and of the various branches of the Association conclude the little book. Almost every State in the Union is represented among the branches, some of them very numerously, while foreign countries are represented by Canada, Chili, England, and Scotland. On the whole Mr. Ballard has a very gratifying story to tell of successful and voluntary effort, and we have no doubt that his little book will lead to a large increase in the Agassiz or similar associations by showing how easy it is to organise and work a "chapter," and the benefit derived from study carried on in this way.

IN the Report of the Bureau of Education of the United States for 1881 (see NATURE, vol. xxix. p. 506) the increase of a class of illiterate population recorded in the census of 1880 was touched upon. A Circular recently issued by the Bureau goes more thoroughly into the subject, and carefully compares the numbers of all the different classes of the population which came under this head at the last census with those of the census of 1870. It is satisfactory to find, from the safe ground of such statistics, that the late alarmist assertions of the terrible growth of an uneducated *proportion* of population is true only of five States out of forty-seven, viz. Maine, New Hampshire, California, Montana, and Nevada. In other States, and on the whole, the ratios of ignorance to education were diminished, even in the Southern States, where so large a proportion of the inhabitants have a tendency to "helpless over-production." Nevertheless, it is true that the *absolute number* of illiterates has increased, in spite of philanthropic as well as Government efforts, by over half a million in these States, and not among the coloured population only. There were 46,000 more in the Pacific States; and thirteen white children out of a hundred throughout the whole States "escaped the combined influences of church, day school, Sunday school, and family teaching." The objection raised in England to the franchise being given to an uneducated

class is urged most strongly in an appendix to this Circular, as being far more dangerous in the United States, where custom exerts no check. Since the danger is equal to the whole Union, while the burden of meeting it falls so heavily on certain States, it is again strongly urged that a part of the expense should be met by national taxation.

THE writer of the second Circular of Information published this year by the United States Bureau of Education trusts that the Shorthand Society of London will throw light upon the history of their art, as the material is quite inaccessible to the American student. Yet his industrious researches there enable him, after speaking of the shorthand invented by Cicero's freedman, and of its revival by Dr. Timothe Bright in Queen Elizabeth's time, to append the names and dates of more than 400 authors of English systems; a catalogue, 100 pages long, of writers and their works on the subject, and 112 alphabets of various dates, from 1602 to 1882. He is able also to quote thirteen monthly publications in the United States and Canada on this subject. It is to be hoped that, in this art as in nature, the result will be the survival of the fittest (Mr. J. Pitman's system already counts its 810th thousand of copies issued), and one is inclined to wonder whether some full and skilful system of denoting sounds might not be worked out, which would render unnecessary the more partial working of phonetic spelling.

THE culture of the tea-tree in Transcaucasia, which has been recently advocated by Dr. Woeikoff, has already been successfully carried out on a small scale for several years—as we learn from a recent communication of M. Zeidlitz to a Russian newspaper. It was an Englishman, Mr. Marr, who has inhabited Transcaucasia since 1822, who brought to a flourishing state the Crown garden at Ozurghety, and embellished it with a number of lemon, orange, and tea trees, these last numbering more than two hundred. After the Crimean war only twenty-five tea-trees were growing in this garden, and according to Mr. Marr's advice they were transplanted to a private estate at Gora, close to Tchakhataour. Since the estate has changed its proprietor, only two tea-trees have remained, but still they continue every year to flower and to give fruit, and M. Zeidlitz is sure that if the culture be seriously tried it might be successful in the valleys of the Koura and Rion.

THE additions to the Zoological Society's Gardens during the past week include a Ring-tailed Coati (*Nasua rufa* ♂) from South America, presented by Miss K. M. Battam; two Patagonian Cavies (*Dolichotis patachonica*) from Patagonia, a Hairy-rumped Agouti (*Dasyprocta prymnolopha*) from Guiana, a Ring-tailed Coati (*Nasua rufa*) from South America, two Rufous Tinamous (*Rhynchotus rufescens*) from Brazil, two Tuberculated Iguanas (*Iguana tuberculata*) from the West Indies, two Huanacos (*Lama huanacos* ♂ ♀) from Bolivia, presented by Mr. Frank Parish, C.M.Z.S.; a Gray Parrot (*Psittacus erithacus*) from West Africa, presented by Mr. E. T. Holloway; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Mr. H. Livermore; two Smooth Snakes (*Coronella lævis*), European, presented by Mr. W. H. B. Pain; a Two-streaked Python (*Python bivittatus*), a Reticulated Python (*Python reticulata*), a Two-banded Monitor (*Varanus salvator*), a Fringed Tree Gecko (*Ptychozoon homalocephala*), a Javan Porcupine (*Hystrix javanica*) from Java, presented by Dr. F. H. Bauer, C.M.Z.S.; two Mountain Ka-Kas (*Nestor notabilis*) from New Zealand, a Three-coloured Lory (*Lorius tricolor*) from New Guinea, a Severe Macaw (*Ara severa*) from Brazil, deposited; ten Common Chameleons (*Chamæleon vulgaris*) from North Africa, two Brazilian Cariamas (*Cariama cristata*) from Brazil, purchased; a Somali Wild Ass (*Equus somalicus* ♂) from Somali Land, received in exchange.

OUR ASTRONOMICAL COLUMN

SCHMIDT'S VARIABLE-STAR IN VIRGO.—Prof. Schjellerup, writing from the Observatory, Copenhagen, on August 9, thus expresses himself with reference to a note which appeared in this column on his identification of the above object:—"On the article that is to be found in NATURE, July 31 last, about this star, allow me to make some essential remarks. The author entirely misconceives the sense of my note in Sûfi. It does not at all concern No. 19 Ptol., but only sets out that Lalande 25086 takes that place where must have been the star which Sûfi saw; and I may yet maintain the correctness of the note. I only ask the author to look at Bremicker's map, Hora XIII.; he will find there that Lalande 25086 has just equal distances from Spica and from *h* Virginis (Ptol. 17), and, what is more, that this distance is nearly one and a half times the distance between Spica and *h* Virginis, very conformably to Sûfi's remark in the text: 'Entre elle (19) et al-simâk (α Virginis) vers le sud-est, il y a environ une coudée et demie, et entre elle et la 17ᵉ il y a la même distance. Avec al-simâk et la 17ᵉ elle forme un triangle isoscèle, cette étoile etant au sommet.' It is also to be remarked that Sûfi has before declared the distance between No. 17 and Spica as 'environ une coudée,' that is, nearly 2° 20'. What is here said about 19 (Sûfi) does not at all agree with the position of No. 19 by Ptolemy, which is also pointed out by Sûfi himself as follows: 'La latitude de cette étoile, indiquée dans le livre de Ptolémée, se trouve erronée, parce que, au ciel, elle se fait voir autrement qu'elle ne tombe sur le globe.'" We are glad to print Prof. Schjellerup's explanation of the purport of his note; it is quite possible that others may have interpreted it as we did.

THE NEW COMET.—Several orbits for this comet have been published in the *Astronomische Nachrichten*, founded for the most part upon the position obtained on the night of discovery, July 16, and on M. Trépied's observations on July 23 and 29, where there appears to have been at first some doubt as to the comparison-star. The middle observation is not well represented by any of these parabolic orbits, and Prof. Weiss conjectures that there is considerable ellipticity, at the same time remarking that a certain general resemblance exists between the elements of the present comet and those of the lost short-period comet of De Vico, observed in 1844, but not found since that year. In the uncertainty which seems to have attached to the observations at Algiers, it would not be safe to speak confidently as to the nature of the orbit, though it may be decided in a very short time.

Prof. Tacchini has kindly communicated the following observation made at the Observatory of the Collegio Romano:—

	Rome M.T. h. m. s.		Right Ascension h. m. s.		Declination ° ' "
August 9, at	8 31 56	...	16 51 20·14	..	−36 56 25·5

The comet was very faint, and the observations, by Prof. Millosevich, are a little uncertain.

The best parabola, according to Prof. Weiss, has the following elements:—

Perihelion passage, August 17·5109 G.M.T.

	° ' "	
Longitude of perihelion	301 57 24	M.Eq. 1884·0
" ascending node ...	357 45 51	
Inclination	7 2 31	
Logarithm of perihelion distance	0·147982	

Motion—direct.

The most reliable elements of De Vico's comet of 1844 are those given by Brunnow in the Ann Arbor *Astronomical Notices*.

BRORSEN'S COMET.—From a note of Prof. Krueger's in the *Astronomische Nachrichten*, it seems that Dr. Schulze has not been able to undertake the calculation of the perturbations of this comet since its last appearance in 1879, and accordingly the rough ephemeris lately given in NATURE is transferred to that journal.

THE FORESTS OF NORTHERN EUROPE

A VERY recent report has appeared on this subject in the shape of a small Blue-Book which deals with the various aspects of the forestry question in certain of the more northerly States of Europe, such as Germany, Russia, Norway, Sweden, Coburg, and Gotha. The Report, which contains matter of great interest in many ways, is the outcome of the proposals of Dr. Lyon, M.P., to rehabilitate the ancient forest system in Ireland; and although the greater part of it deals with the

administrative and commercial results, in themselves of great value, many facts are elucidated which bear upon the natural history of the countries under discussion. The Duchy of Gotha contains a forest area of 32,054 hectares, of which at least 94 per cent. are massed together in the Thuringian Forest, whilst the remainder cover the height above the plains, at an elevation of about 900 metres above the sea. The geological formation of these heights is for the most part Lower New Red interspersed with thick veins of porphyry, while that on which the plain forests are situated is limestone. At least 85 per cent. of the Gotha trees are pine, the remainder consisting of larch, oak, maple, ash, birch, and elm. The Duchy of Coburg does not possess half the forest area of Gotha, there being only 15,718 hectares altogether, of which 86 per cent. is pine. Considering the minuteness of information which is gathered together by most of the German Departmental Bureaus, it is surprising how difficult it is to obtain statistical knowledge on the subject of forests, the reason being that each State has its own Department of Agriculture, quite irrespective of the Imperial Administration. Prussia, however, seems to have been more awake than the others, to the desirability of attempting to cultivate other than indigenous trees in the kingdom; and in the Budget for 1880, no less than 50,000 marks (2500*l.*) was set aside for the purpose. The following list was made out of new trees, but as there has not been any further mention of their introduction in subsequent Reports, it is uncertain how far the proposal was really carried out. The trees were as follows:—

Name	Habitat
Pinus rigida	North America, eastern portion.
Thuja gigantea	
Juglans nigra	
Carya alba	
C. amara	
C. aquatica	
C. tomentosa	
C. porcina	
Quercus rubra	
Populus monilifera	
Abies Douglasii	North America, western portion.
Pinus ponderosa	
Cupressus Lawsoniana	
Juniperus Virginiana	
Acer Negundo	
A. saccharinus	
A. dasycarpum	
Betula lenta	
Abies Nordmanniana	Caucasus.
Pinus Laricio	Southern Europe.
Picea sitchensis	Japan.

The estimated area of forest land in European Russia is about 146,460,000 dessiatines (1 dess. = 2·69 acres), or 33 per cent. of the total area of the country, compared with which Austria has 29 per cent., Germany 26, France 19, Italy 18, and Turkey 14. It is a drawback to Russia that her forests are so unevenly concentrated, at least three-fifths being situated in four Governments, leaving but two-fifths to the other forty-five. As a rule, the further one travels south in Russia the less forest is met with, the Governments of Archangel, Wolgoda, Olonetz, and Perm possessing 60 per cent., while in those of Poltawa, Bessarabia, and the country of the Don Cossacks, there is not more than 4 per cent. It is an undoubted fact that Russian timber is on the decrease; and ten years ago M. Aschakow in his evidence before a Commission to inquire into the condition of the forests in the Ufa, stated that the whole of that part of the country was threatened with an absolute want of wood, hundreds of thousands of trees being stripped for the sake of the bark and the roots. Naturally the evil does not stop here; but the climate also shows a considerable change—the rivers, such as the Bielaia, showing each year a smaller volume of water. Floods are more frequent, property is destroyed to an alarming extent, the beds of the rivers silt up, and the navigation becomes annually more and more uncertain. From observations made at Kieff, the winter lasts longer, and the harvests are not so productive as of yore; while Dr. Grimm notes that rivers which once had a reputation for abundance of fish, the banks of their rivers being well covered with timber, are now as deficient as formerly they were rich, and he attributes the change to the dearth of insects, whose larva furnish food for the fish. Another evil arising from the destruction of the forests is the much greater liability to hailstorms; and in this respect the same complaint comes from France, Germany, and Switzerland. Indeed, districts that were once wooded, rarely, if ever, suffered from hailstorms; and the converse has been noted that, where new trees have grown up, the storms have been less and less severe.

So general has been the conviction that this forest destruction is causing serious damage to the country, that a society has been formed at Moscow to consider the question, and engineers have been sent with a view of ascertaining the height of the water in the rivers during the spring, the changes in the number and size of the lakes, the changes which have taken place in the character of the summer and winter seasons, particularly as affecting the vegetation and the growth of plants. M. Wagner, in an article in the *Novoe Vremya*, 1882, considers that the systematic forest waste will lay Western Russia open to the action of the south-east wind, and thus bring undue dryness and contagion from Central Asia; and according to the latest accounts of the advance of the Siberian plague, M. Wagner's prognostications seem in a fair way of fulfilment.

The climatic conditions of Russia are such as to allow a great variety of trees to flourish. If a line be drawn from Orenburg towards the west, through the Governments of Samara, Pensa, and Tamboff, as far as Tula, and thence to Charkoff, Kieff, and Volhynia, the deciduous trees will be found to predominate to the south, and the coniferous trees to the north. As far as 67° N. lat. *Pinus sylvestris* is the most universal tree, being found in the south, indeed, only in isolated patches. It extends northwards as far as 70° N. lat., and eastwards as far as the Petchora, its southern boundary being at 44½°, though, passing over the steppes, it is again seen in the Caucasus at from 41½° to 43°. *Abies excelsa* is the next common, being found in Finland as far north as 68¾°, while in the east the predominating tree is *A. obovata*. *A. sibirica* extends to 64°, and not further south than Nijni Novgorod. The larch (*Larix europæa*) is only met with in Poland, though *L. sibirica* inhabits the Government of Olonetz, Nijni Novgorod, and the Ural as far as the river Sakmara (51¾°), and is in high repute for ship-building purposes. The cedar (*Pinus cembra*) extends north-east to 64½°, and also in the northern part of Orenburg to 51°. There are large forests of this pine in Perm and Volgoda, and an extensive trade is carried on in the exportation of cones. As to the deciduous trees, the birches (*Betula alba*, *B. pubescens*, *B. verrucosa*, *B. fruticosa*, and *B. nana*) are very general throughout Russia, being found on the Petchora in 67° N. lat., as well as in the Crimea and the Caucasus. The oaks (*Quercus pedunculata*) have the same range southward, but are not met with on the north further than St. Petersburgh and Southern Finland, and not at all east of the watershed of the Ural. The variety known as *Q. pedunculata tardiflora* grows in the Governments of Kieff, Poltava, Charkow, and Voronetz, and is the only oak that flourishes in the Crimea. *Q. robur* and the beech (*Fagus sylvatica*) have their homes in Poland, Podolia, Volhynia, Bessarabia, the Crimea, and the Caucasus. The aspen (*Populus tremula*) is found all over the land as far as 66°, and is a valuable industrial tree, being used in paper-making. The lime-tree also (*Tilia parvifolia*) is valuable in the bast manufactories and for making matting, and is found from 64° as far as Volgoda and Perm and in the Governments of Kostroma, Kazan, and Simbrisk. The red beech flourishes at heights varying from 1500 to 4000 feet above the sea-level, and, with the white beech (*Carpinus betulus*), is chiefly found in the south-west of the Empire, and also in the Caucasus and Crimea. There are large forests in the neighbourhood of Kieff and Poltava, entirely composed of this tree. The elms (*Ulmus effusa*, *U. campestris*, and *U. suberosa*) usually frequent the south, though not in profusion; but the ash (*Fraxinus excelsior*) is much more plentiful, and is particularly valuable, as affording shelter for the Spanish fly, the exporting of which is a somewhat extensive industry. The maples (*Acer platanoides* and *A. tataricum*) are tolerably plentiful in all parts, though not as forest trees. The same may be said of the alder (*Alnus incana*), the willow, wild apple, pear, and plum.

The average annual produce of the Russian forests is about 600,000,000 cubic feet, at which rate the yield of a dessiatine is not more than six cubic feet, a poor result when compared with other countries, Prussia giving at the rate of 84·7 cubic feet a year, Bavaria 131, and Saxony 165. It is singular, however, that where the extent of productive forest in Russia is smaller, the yield per dessiatine is greater, the average of the central provinces being 60 cubic feet, and in the south 37, while in the

north it scarcely amounts to 3 cubic feet. Nor is the return very satisfactory from a pecuniary point of view, most of the Governments being far under one rouble per dessiatine, though a few can show better results, those of Moscow, Kursk, and Voronetz being 3½ roubles, of Charkow 5½, Tula 6·16. But the general value is not as satisfactory as in other countries, Prussia showing an equivalent of 2½ roubles, Bavaria 4½, Saxony 10, and France 9. One of the most useful developments of tree cultivation in Russia has been the formation of plantations along the railway tracks, about 2000 dessiatines having been already covered in this way on the Kursk-Charkoff-Azov, the Kozloff-Voronetz-Rostoff, the Orel-Griasi and Fastovo lines, the object being of course the protecting of the rails from snowdrift. M. Sredinsky, the inventor of this very successful system, considers that seven rows of trees are sufficient for this purpose, and on this calculation one verst would require 33,000 plants, of which 9000 must be trees, and the remaining 24,000 shrubs. The trees which he finds best adapted for this purpose are elm, ash, oak, white and yellow acacia, maple, white thorn, hazel (*Corylus avellana*), wild plum, gleditschia, mulberry, elder, &c., but along the Sumi Railway in the Government of Charkoff, *Pinus sylvestris* has been planted, and does well. Tree-planting has also proved invaluable for fixing the sand plains at Aleschki on the Dnieper, the best for this purpose being *Salix acutifolia*, *Genista tinctoria*, *Ulex europæus*, *Prunus spinosa*, and *Pinus maritima*. When Russia first got possession of the Crimea, the banks of the Dnieper were wooded for at least seventy versts; but, as colonisation extended and population increased, the herds and flocks destroyed the roots of the trees, and thus allowed the formation of these sand plains, which comprise 139,000 dessiatines. Of these, some 20,000 are fairly covered with *Salix viminalis*. Birch are found on about 10,000 dessiatines, while at least 34,000 are of the pure sand.

THE AMERICAN INITIATIVE IN METHODS OF DEEP-SEA DREDGING[1]

THE published records respecting the use of dredges for natural history purposes carry us back to scarcely more than a century and a quarter ago, when Otho Frederick Muller, a prominent Danish naturalist, began his studies of the aquatic life inhabiting the coasts of Norway and Denmark below the shore-level. The dredge he used, a very simple affair, was, so far as we know, the first one ever devised for the special needs of the naturalist; and yet, with only a single important modification as to the shape of the frame, it has been handed down to our time as the most efficient appliance for the ordinary purposes of dredging.

As described and figured in 1779, it consisted of a plain, rectangular iron frame, with all four sides of equal length, and bevelled to sharp edges in front, forming the mouthpiece to a large and open net. Four handles extended forward from the angles, and met in a single ring for the attachment of the drag-rope. The principle defect of this dredge consisted in its very wide mouth, permitting the easy escape of specimens both while dragging and during the hauling in.

Although Muller's researches were confined to shallow water, apparently not exceeding a depth of thirty fathoms, they established a precedent for subsequent operations, and afforded proof of the value of submarine collecting.

This new field of exploration did not, however, begin to enlist the active services of working naturalists to any extent until about the third or fourth decade of the present century, since which time the interest in marine zoological research has rapidly increased, and our knowledge of the sea-bottom has been extended to the deepest-known areas. For the first thirty or forty years the improvement in methods of work scarcely kept pace with the progress of knowledge regarding the inhabitants of the sea; and it is only within the past fifteen years that the methods of deep-sea dredging have been at all perfected.

To Dr. Robert Ball of Dublin, who was afterwards associated with Prof. Edward Forbes in his memorable explorations, has generally been given the credit of having devised, about 1838, the improved form of naturalists' dredge, in nearly the same shape in which it is used to-day. However that may be, it was about the year last mentioned that both European and American naturalists entered actively into the study of the sea-bottom; and the history of their various exploits down to the present time affords an exceedingly interesting chapter, upon which the subject of our paper permits us to touch but slightly.

It may be well to remark, however, that the character and results of European, and especially British, exploration are much more widely and popularly known than are those of our own country. The reason is obvious. The active mercantile pursuits of a young and progressive people have naturally made them less appreciative of scientific facts and results than the inhabitants of many older countries, where business interests have fewer claims upon all classes. There has been but a slight demand for popular writings upon such an unpractical subject, and the plodding naturalist has generally been content to record his observations and methods where they were accessible only to his brother-workers. For this reason American naturalists have not received the credit which is their due, either at home or abroad; and much of the honour that justly belongs to them has passed into other hands.

So far as concerns the general public, this is not to be wondered at, when we consider that the only popular accounts of deep-sea dredging explorations obtainable in this country are of English origin. But the same excuse does not hold good for the working naturalists of any country, including our own; as the progress of American deep-sea research, and the improvements in methods for carrying it on, have in nearly all instances been duly and promptly recorded in the proper channels to insure wide and timely distribution.

Since the very beginning of activity in this branch of investigation, American workers have not been far behind those of any European country; and their record is as creditable. Dredging was carried on by the Wilkes U.S. Exploring Expedition during the early part of its cruise, beginning in 1838; and at about this same time a few of our most earnest naturalists were using the dredge at home. The late Dr. William Stimpson, one of the most intelligent observers in this branch, and whose name is closely linked with several important explorations, began his career in Boston Harbour between 1848 and 1850; his first instructions having been received from Dr. W. O. Ayres, who began dredging fully ten years before. Stimpson's researches were largely conducted under Government auspices; and the collection of submarine specimens resulting from his labours, distributed over many portions of the Atlantic and Pacific Oceans, was probably one of the very largest of its kind that had been made, up to the time of its unfortunate destruction by fire at Chicago, in 1871. The loss of these collections, and of all the voluminous manuscript reports treating of them, followed by the sad death of the author, has deprived our country of a most important chapter in the history of submarine exploration.

The sixth decade of this century, however, brought out many additional investigators, and a fresh impetus was given to the work, which has since been expanded and developed to such an extent as to establish beyond all question American precedence in the methods of deep-sea research at least, both as regards dredging and sounding.

From among the more energetic and successful of our modern dredgers may be mentioned Prof. A. E. Verrill of Yale College, whose dredging studies began in 1864, on the coast of Maine, and who, since the organisation of the U.S. Fish Commission, has been its main helper and adviser in all matters pertaining to submarine research, the special direction of the dredging operations having been intrusted to him from the beginning. His earlier experiences gave him a clear insight into the requirements of the new project, and enabled him to devise many valuable appliances, and improve upon those which had been in use. To his zealous and untiring efforts is due much of the perfection in present methods of work.

In 1867 Mr. L. F. de Pourtalès, of the U.S. Coast Survey, began the extensive series of deep-sea explorations off the southern coast of the United States, which were carried on for several years, and subsequently led to the eventful cruises of the steamer *Blake* between 1877 and 1880, resulting in an entire revolution in the methods of deep-sea dredging and sounding. The investigations of Mr. Pourtalès anticipated by a year those of the English steamers *Lightning* and *Porcupine*, which have been so widely described, and were preceded by only one series of systematic dredgings in equal depths of water—those of the Professors Sars, father and son, of Norway. But little credit for this fact has been received from naturalists abroad, the date of Mr. Pourtalès' first cruise being generally regarded by them as 1868, although his first paper, descriptive of the character of his work and of many new forms of deep-sea animals, appeared in

[1] From *Science*.

December 1867.[1] His collections, representing principally the fauna of the Gulf Stream off Florida, gave new and interesting results, going farther to prove the existence of a rich and diversified deep-sea fauna, different from that of the shore regions, than any previously obtained.

That these dredgings were not undertaken to please the passing whim of some over-enthusiastic naturalist, but were as deliberately planned and carried out, and as successful in their results, as those of the English steamers which followed them in conception, a reference to the official publications of the Coast Survey will sufficiently prove. As substantiating this statement, we may be pardoned for quoting a short paragraph from the report of Mr. Pourtalès, above referred to (December 1867), in which the plans and objects of the new explorations are briefly stated. This would not be called for, were it not that it is this identical report which has been so utterly ignored by European writers, and equally overlooked by many Americans. Had it only been written in popular language, and been published with copious illustrations, it might have received the credit which has been denied it; but such channels of publication are seldom deemed necessary to establish priority in scientific research.

The plan of operations, according to Mr. Pourtalès, was as follows:—

"The present Superintendent of the Coast Survey, Prof. B. Peirce, has lately directed the resumption of the investigations of the Gulf Stream, so successfully inaugurated by his predecessor, but interrupted for several years by the war. Besides observations of the depth, velocity, and direction of that current, and the temperature and density of the water at different depths, the researches will be extended to the fauna of the bottom, of the surface, and of the intervening depths. Not only will an insight be thus obtained into a world scarcely known heretofore, but that knowledge will have a direct bearing on many of the phenomena of that great current. Thus a new light may be thrown on its powers of transportation from shallow to deeper water or along its bed, on its action of forming deposits in particular localities, or on its possible influence on the growth of coral-reefs on its shores."

In a subsequent passage he summarises his first season's results in the following terse remarks, the italics being his own:—

"However, short as the season's work was, and few as were the casts of the dredge, the highly interesting fact was disclosed, that *animal life exists at great depths, in as great a diversity and as great an abundance as in shallow water.*"

Early in the following year (1868) the same explorations were resumed, and they were continued through 1869.

It may be thought that we have departed too widely from our subject in discussing with so much detail the progress of American research during a period in which no great improvements were made in methods of work on this side of the Atlantic; but how could we have better furnished proof of the rapid growth of interest in such matters, and of the maturing of ideas which prepared the way for the important changes marking the next decade.

There is, however, one noteworthy addition to the collector's outfit made in this period, which deserves special mention. On one of the dredging cruises of the English exploring steamer *Porcupine*, between 1868 and 1870, Capt. Calver, the naval officer in charge, attached several of the common deck-swabs to the end of the dredge-net, with the expectation that, in sweeping the ocean-bottom, they would securely entangle all the rough and spiny objects lying loose within their path. His fondest hopes were realised, and the novel experiment, suggested by often finding such objects as sea-urchins, corals, and sponges, adhering to the exterior of the dredge-net, and even to the lower part of the drag-rope, gave origin to one of the most efficient implements of modern deep-sea research.

When the beam-trawl, a well-known English appliance for the capture of bottom-fish, was first adopted into the outfit of the marine zoologist, we are unable to state; but it does not appear to have ever been extensively and systematically employed in scientific research until so used by the U.S. Fish Commission, beginning in 1872. It was afterwards used by the *Challenger* from 1873 to 1878, and now greatly excels the dredge in the extent and value of its results, wherever the ground is suited to its use.

The year 1871 was signalised by the organisation of the U.S. Fish Commission, one of the most important scientific establishments of modern times for marine zoological work. Although instituted primarily for the investigation of fishery matters, it has, through the wise and liberal policy of its Director, Prof. Baird, accomplished most valuable results for marine biology. The latter department has been sedulously fostered, in the belief that its results would have an important bearing upon the practical questions at issue. No pains have been spared to perfect the methods of research, and many valuable contributions have already been made to the marine collector's outfit. These are briefly described below, and, as the history of the Commission is already well known to most readers, we need refer here to only a few points which have marked its progress.

The earlier explorations were carried on mainly by means of sail-boats, and were confined to comparatively shallow water. From 1873 to 1879 a naval tug was placed at the disposal of the Commission every year; but in 1880 the steamer *Fish Hawk*, a twin-screw propeller of 205 tons (n.m), was built expressly for the combined purposes of fish-hatching and dredging. Its small size and light draught prevented long trips at sea, but it was well adapted for deep-sea work, and was supplied with all the improved appliances, as well as those which had originated with the Commission, including wire rope, then recently introduced by the Coast Survey. In 1883 the steamer *Albatross*, described in vol. ii. of *Science* (pp. 6, 66), was completed, and made her first successful cruise in the spring of that year. Her log for the summer of 1883 records the deepest trawling yet made in the Atlantic Ocean, the depth having been 2949 fathoms, and the results successful. Brief accounts of her dredging cruises under Lieut.-Commander Tanner, U.S.N., have appeared from time to time in late numbers of *Science*.

While the Fish Commission claims priority for many improvements in apparatus primarily intended for depths under a thousand fathoms, it willingly yields the palm for deep-sea improvements to the U.S. Coast Survey, especially in the persons of Commander Sigsbee, U.S.N., and Mr. Agassiz. The explorations of the steamer *Blake* from 1877 to 1880, in which the methods of deep-sea dredging and sounding were completely revolutionised, mark one of the most important stages in the progress of marine research. Wire rope was substituted for hemp, the dredge was altered to adapt it to the soft bottoms of deep water, on which dredging results had always been uncertain, and the beam-trawl was made reversible. The methods of handling and reeling the rope were also perfected. These changes and additions were briefly described and figured from time to time as work progressed in the *Bulletin* of the Museum of Comparative Zoology, at Cambridge, by Mr. Agassiz and Mr. Sigsbee, and were afterwards fully discussed by the latter in one of the most elaborate and instructive reports ever dedicated to the methods of deep-sea research.[1] It is a quarto volume of 208 pages and 41 plates, describing the sounding and dredging appliances used by the *Blake*, and which, for the greater part, were devised or improved during her dredging cruise. So far as her dredging appliances are concerned, the credit for changes made belongs mostly to Mr. Sigsbee and Mr. Agassiz, the former having been in command of the expedition, and the latter in charge of the natural history operations.

During the seventh decade, European explorers were not idle, and numerous deep-sea expeditions were fitted out. Most notable among these was the cruise of the British ship *Challenger* around the world between 1873 and 1878. Her scientific results were most interesting; but the older methods of deep-sea work were not greatly altered, although the practicability of using the beam-trawl successfully in the deepest water was fully demonstrated.

In 1881 the French Government inaugurated a series of submarine explorations in the Atlantic Ocean and Mediterranean Sea; for that purpose fitting out a small naval vessel, the *Travailleur*, and placing the management of affairs in the hands of a competent scientific staff, under the directorship of Prof. A. Milne-Edwards. These investigations were continued by the same vessel during 1882, the appliances and methods of work having apparently been patterned after those generally recognised in Europe. In 1883 a larger vessel, the *Talisman*, was assigned to the work, and operations were established on a much grander scale than before.

For an account of these explorations, descriptive of the methods of work and general results, we are indebted to the last volume of *La Nature*, a French journal of the character of

[1] *Bulletin* Mus. Comp. Zool., Cambridge, vol. i., 1863-69, pp. 103-120.

[1] "Deep-Sea Sounding and Dredging: a Description and Discussion of the Methods and Appliances used on Board the Coast and Geodetic Survey Steamer *Blake*." By Charles D. Sigsbee, Lieut.-Commander U.S. Navy Assistant on the Coast and Geodetic Survey. (Washington, 1880.)

Science, which began in a January number the publication of a series of articles by one of the naturalists who accompanied the steamer.[1] Coming from such an authoritative source, we are led to regard these papers almost in the light of a semi-official report, and look to them for at least a correct statement regarding the origin of their methods of work, inasmuch as these matters are discussed in some detail, and with evident pride at the completeness of the outfit. That the outfit was complete no one who is at all posted on the subject can deny; for nearly all of the many improvements introduced by the Coast Survey and Fish Commission prior to 1880 are most faithfully copied, and most heartily praised for their perfect adaptation to the requirements of research.

We glance through the several pages of the report for at least some slight acknowledgment on behalf of American inventive skill; but beyond a brief statement to the effect that the hoisting-engine "was of the same type as that employed by Mr. Agassiz," and that he also "used with good results the common form of beam-trawl," we are left to infer that the entire outfit was of French origin; and such must be the impression of every one who reads these papers. In fact, in several instances, credit is explicitly bestowed on French inventors for certain of the appliances which do not differ in any essential features from the corresponding American patterns.

What is to be gained by thus appropriating to the credit of a nation what properly belongs to another and a friendly one, by all the rights of international courtesy, it is difficult to understand, and especially so in this age of supposed enlightenment, when every important discovery is carried with lightning rapidity to all parts of the civilised world. The field of marine research is sufficiently broad to engage the entire attention of all the naturalists who have yet entered it; and the frequent manifestations of jealousy on the part of foreign, and especially French, investigators, which often result in wholly ignoring the works of an able American author, can but retard progress instead of aiding it.

Proofs of the superior excellence of American methods of deep-sea research may be found in every important scientific library of Europe as well as this country; and at the two most prominent International Fisheries Exhibitions of the world—those of Berlin in 1880, and London in 1883—all of the American appliances were displayed, and received the highest awards. They have therefore been made sufficiently well known to establish their merits before the scientific world; but, as no descriptions of them have yet been published for the benefit of the general public, we propose in future numbers of *Science* to give accounts of their construction, and of the causes which lead to their introduction.

RICHARD RATHBUN

WHY TROPICAL MAN IS BLACK

THERE are few subjects the explanation of which has taxed the ingenuity of man more than the existence of extremes of colour in different sections of the human race. Tradition has attributed the dark race to one of three brothers, the other two being progenitors of the opposite hue, without at the same time offering any solution of the variation from a common

Physiologists have vaguely asserted that a black skin is best suited to a hot climate, but do not attempt to reconcile the fact that a black coat is certainly the least adapted to the same condition. Evolutionists would doubtless say that in those early days when man in the dense forests of the time was fighting his brave struggle of brain against fangs and claws, the dark skin mingling with the shadows of the overhanging foliage gave him a chance of survival; but this reaches the conclusion that the first men were black, and that all white men proceeded out from these.

Yet even if this be so, and if the dark skin served only for concealment, why on the burning tablelands and treeless undulations of Central and Southern Africa, where there is scarce a bough to shelter him, has man for so many thousand years preserved a colour which has become the standard of all blackness? Surely there must be some other explanation of the fact that man beneath the vertical rays of a tropic sun has persisted in maintaining a hue of skin which would appear to have the effect only of absorbing and accumulating the intense heat of his surroundings. Some reason why the ryot of India can labour in the plains clad only in the scantiest loin-cloth, and why the African can limit his full dress to a few inches of monkey-tails.

The rapidly accumulating evidence of the practical utility of every peculiarity, and the proofs that nature, by hoarding up a little of each individual advantage through countless generations, has arrived at the best condition for each environment, compel us to realise the fact that in the tropics darkness of skin contributes to survival.

That this colour will absorb heat more than any other is as true of the skin of a man as of the roof of a house; therefore the anomaly is reached that in the tropics he is fittest who is hottest, so long as heat is regarded as the only factor in the consideration. But that one cannot live by heat alone is as true of the animal kingdom as of the whole vegetable world. Light, the twin stimulant of life, because perceptible to our consciousness by its action on a specialised nerve, has been too much limited in our conceptions of its influence to that duty only.

The gigantic processes of nature by which the great vegetable world, past and present, has been built up, the oxygen of water divorced from its hydrogen in the leaves of plants, and carbonic acid resolved into its constituents, were and are accomplished by the light-waves of the sun; and yet in the animal kingdom the action of these waves upon the eye is held to be almost their sole effect.

The craning offshoot of a window-plant, the twisted leaves of an indoor flower are sufficient evidence of the resistless power of light, and the proofs of its effect on man are as numerous as those of its action on plants; the mode only of that action is the mystery, and yet if this can be even partially explained, enough may be attained to show why those in whom a portion of the rays of the glaring tropic sun are blocked at the surface are best adapted for survival beneath its vertical beams.

As has been expressed by Prof. Tyndall ("Atoms, Molecules, and Ether Waves," *Longman's Magazine*, Nov. 1882), "We know that all organic matter is composed of ultimate molecules made up of atoms, and that these constituent atoms can vibrate to and fro millions and millions of times in a second." Nerve is organic matter, and "whether we meet with nerve tissue in a jelly fish, an oyster, an insect, a bird or a man, we have no difficulty in recognising its structural units as everywhere more or less similar. These structural units are microscopic cells and microscopic fibres, the function of the fibres is that of conducting impressions (represented by molecular movements) to and from the nerve cells, while the function of the cells is that of originating those of the impressions which are conducted by the fibres outwards," (*vide* "Mental Evolution in Animals," Romanes).

We can conceive then that the way in which a nerve-fibre conveys to a more central nerve-cell an impression from the surface is by rapid vibration of its component molecules. Such vibrations can be rudely originated by contact, pressure, or such like stimuli, till they give rise to feeling, or, if severe, to pain, but they can be not only improvised, they can be communicated. The simplest illustration of vibrations being communicated is when a piano is opened and sung into; whereupon the string whose tension coincides with the uttered note will take it up and pass it on in sound. If then vibrations were taking place in the immediate vicinity of the sentient extremities of nerves all over the surface of the body, the same would be expected to occur.

The waves of light and heat follow each other at similar rates through the luminiferous ether.

Man lives at the bottom of a measureless ocean of this subtle medium, and is, in common with all else in the universe, permeated by it. "When, therefore, light or radiant heat impinge, like the waves of sound just adverted to, their waves select those atoms whose periods of vibration synchronise with their own periods of recurrence, and to such atoms deliver up their motion. It is thus that light and radiant heat are absorbed." (Tyndall).

Is it not from this easily intelligible how heat-waves notify their existence and intensity along the surface fibre to the central nerve cell, and so enable the animal to avoid their action, if excessive, or seek their increase, when deficient. And shall it be said that while the heat-waves are thus received, and responded to, through every instant of existence, their fellow-workers, the waves of light, are practically inert except for the stimulation of the one specialised nerve of the eye?

By going from the complicated and compound to the structureless and simple, the question can be answered in no uncertain way.

[1] For an abstract of the portion relating to the apparatus employed, see *Science*, No. 62.

In some of his recently published experiments, Engelmann found that many of the protoplasmic and unicellular organisms are affected by light, and when the first animals possessed of organs of special sense, viz., the jelly-fish, (Medusæ), are reached it is found that one particular Medusa (*Tiaropsis polybiademata*) always responds to strong luminous stimulation by going into a spasm or cramp (Romanes).

But there is a still stronger argument in favour of the powerful action of light on the nerves of the skin in the fact that, as Prof. Heeckel says, "the general conclusion has been reached that in man, and in all other animals, the sense organs as a whole arise in essentially the same way, viz. as parts of the external integument, or epidermis." In fact, that nerves which now see could once but feel. That the highly sensitive optic nerves are but nerves of the skin, whose molecules once could vibrate only in consonance with the large ultra-red waves of heat, whereas now their molecules have become attuned to the shorter waves of the visible part of the spectrum.

Surely, then, if any one of the nerve-endings of the skin indiscriminately can be specialised for the recognition of light, whether at the margin of the swimming disk in the jelly-fish, at the point of the ray in the star-fish, on the fringe of the mantle in the shell-fish, or on the back in some species of snail, it must be conceded that in the first instance all surface nerves must feel the influence of that agent by which they are to be hereafter exalted. And this has been reduced to a demonstration by Mr. Darwin in his investigations on earthworms, which, although destitute of eyes, are able to distinguish with much rapidity between light and darkness, and as only the anterior extremity of the animal displays this power he concludes that the light affects the anterior nerve-cells immediately, or without the intervention of a sense-organ. But a yet more wondrous lesson is to be learned from the steps which Nature takes for the exaltation of a heat-responding nerve into one capable of vibrating in harmony with the shorter waves of light.

The only external agents available are heat and light, and by these, with such local adaptations as are possible, the conversion must be brought about.

Seeking again from the lowest organisms the secrets of the highest, it has been found by Engelmann that the simplest creature which responded to luminous stimulation was the protoplasmic *Englena viridis*; moreover, that it would only do so if the light were allowed to fall upon the anterior part of the body. Here there is a pigment spot, but careful experiment showed that this was not the point most sensitive to light, *a colourless and transparent area of protoplasm lying in front of it being found to be so.*

From this, the most rudimentary, through the pigmental bodies round the margin of the swimming disk of medusæ, and the pigmented ocelli at the tips of the rays in star-fish, to the lowest vermes, in which Prof. Haeckel finds the *usual cells sensitive to light separated by a layer of pigment cells from the outer expansion of the optic nerve*, we meet with the same arrangement ever progressing upwards, viz., transparency immediately in front of the part to be exalted, and pigment immediately behind it, and are left to infer from the object ultimately attained what is the reason of this primary adaptation.

Nature has made the most of her two factors, by exposing the selected tissue to the continued impinging upon it of the waves of light, while at the same time securing not only the transmission through it of the waves of heat, but their constant accumulation behind it, thereby causing the molecular constituents of the protoplasm to be thrown into the highest rates of vibration possibly obtainable with the means at disposal, and undoubtedly more rapid than those of any protoplasm not so situated; till little by little, by the survival here and there of individuals who had derived some benefit from inherited increase of sensitiveness in the exposed parts, the time arrived when the advantage became permanent in the species, and the foundation was laid in a transparent atom of protoplasm lying in front of a speck of pigment, of those wondrous organs which in æons of ages afterwards were to enable man to look upon the universe and to behold that it was good.

Such is what light and heat in unison have wrought, and is it to be supposed that their action on the surface nerves is less powerful now than ever? Is it not more reasonable to think that a larger number of specialised nerves not being an advantage have not been developed, and that though we are unconscious of the power of light upon our bodies, yet that analogy points to the fact that to it, when combined with heat, we owe the highest exaltation of our keenest sense?

Recognising thus the effects of simultaneous light and heat when their influence is concentrated by a local peculiarity on a particular part, must it not be evident that in an individual unprotected by hair and unscreened by clothes, living beneath the vertical rays of an equatorial sun, the action of these two forces playing through a transparent skin upon the nerve-endings over the entire surface of the body, must be productive of intense, but at the same time disadvantageous, nerve vibrations, and that presumably such individuals as were least subject thereto would be best adapted to the surroundings?

Nature, therefore, having learned in ages past that pigment placed behind a transparent nerve will exalt its vibrations to the highest pitch, now proceeds upon the converse reasoning, and placing the pigment in front of the endangered nerve reduces its vibrations by so much as the interrupted light would have excited, a quantity which, though apparently trifling, would, when multiplied by the whole area of body-surface, represent a total of nervous action that if continued would soon exhaust the individual and degrade the species.

Thus it is that man, though so many generations have come and gone since the days of his weaponless struggles with the beasts of the forest, still retains in its full strength that colour of skin which, while it aided him materially in his early escapes, is now continued because it has a more important office to fulfil in warding off the millions of vibrations a second which would otherwise be poured in an uninterrupted stream upon his exposed nervous system.

Again, the chemical power of light expressed in degree is, according to Professor Bunsen in Berlin, on the 21st of June at 12 o'clock, 38°, while at the same place and time on the 21st of December it is but 20°, that is, that the difference in the angle at which light strikes the same spot in December and in June causes its chemical effect to be almost doubled. What then must be its potential difference all the year round in the latitude of London and in that of Sierra Leone?

If, therefore, light be a necessary factor in the development of animal life, and be of sufficient intensity to attain the required end in the northern position of England, it must of necessity be at the equator immensely in excess, all other things being equal of what is needed, and it would be a reasonable expectation that could unclothed man be traced through the parallels of latitude northwards in distinct tribes that never intermingled with those beyond, the colour of the various sections would lessen in direct proportion to their distance from the equator, modified only by such local conditions as materially influenced the effect of light, or the action of light and heat combined.

And this is forcibly corroborated by the facts put forward in Carpenter's "Physiology," p. 985: "It may be freely admitted that among European colonists settled in hot climates such changes do not present themselves within a few generations; but in many well-known instances of earlier colonisation they are very clearly manifested."

"Thus the wide dispersion of the Jewish nation and their remarkable isolation, maintained by their religious observances from the people among whom they live, render them peculiarly appropriate subjects for such observations, and we accordingly find that the brunette complexion and dark hair which are usually regarded as characteristic of that race are frequently superseded in the Jews of Northern Europe by red or brown hair and fair complexion, whilst the Jews who settled in India some centuries ago have become as dark as the Hindoos around them."

Finally, there is in a footnote to the same page an extraordinary physiological demonstration of the truth of the proposition that skin colour is in direct proportion to light-rays, which is as follows:—

"A very curious example of change of colour in a negro has been recorded on unquestionable authority. The subject of it was a negro slave in Kentucky, æt. forty-five, who was born of black parents, and was himself black until twelve years of age. At that time a portion of the skin an inch wide encircling the cranium just within the edge of the hair gradually changed to white, also the hair occupying that locality; a white spot next appeared near the inner canthus of the left eye, and from this the white colour gradually extended over the face, trunk, and extremities until it covered the entire surface. The complete change from black to white occupied about ten years, and but for his hair, which was crisp and woolly, no one would have supposed at this time that his progenitors had offered any of the characteristics of the negro—his skin presenting the healthy vascular appearance of a fair-complexioned European. When he was about twenty-two years of age, however, dark copper-

coloured or brown spots began to appear on the face and hands, but *these remained limited to the portions of the surface exposed to light.*"

May it not therefore be claimed that there is much foundation for the suggestion that the black skin of the negro is but the smoked glass through which alone his widespread sentient nerve-endings could be enabled to regard the sun?

NATHANIEL ALCOCK,
Surgeon-Major, Army Medical Department.

Since the foregoing was written there has appeared in the *British Medical Journal*, July 26, a most valuable paper by Dr. Gresswell on "Some Effects of Variations of Light," which sums up in these words, "We are tempted to conclude that light and heat impose each its own effects upon plants, as they do upon animals," and that "light is a stimulus direct as well as indirect."

SCIENTIFIC SERIALS

Atti della R. Accademia dei Lincei, May 18.—On the molybdate of didymium, by Alfonso Cossa.—On the geological constitution of the Maritime Alps, by D. Zaccagna.—On some psychological difficulties that may be solved by means of the idea of the infinite, by Francesco Bonatelli.—Remarks on the Oriental manuscripts of the Marsigli Collection at Bologna, with a complete list of the Arabic manuscripts in the same collection, by Baron Victor Rosen.—The Ligurians associated with the barrows of the first Iron Age found in the district of Golasecca, Lombardy, by Luigi Pigorini.—Note on Bartolomeo da Parma, an astronomer of the thirteenth century, and on a treatise by him on the sphere preserved in the Victor Emmanuel Library, by Enrico Narducci.—Report on the antiquities discovered in various parts of Italy during the month of April, by S. Fiorelli.—Meteorological observations made at the Observatory of the Campidoglio during the month of April.

June 1.—Obituary notice of A. Wurtz, by S. Camizzaro.—On the expansion of sulphuric ether under various pressures, by G. Pietro Grimaldi.—On the physiology and pathology of the supra-renal capsules, by Guido Tizzoni.—Analysis of a silicated hydrate of baryta, by Alfonso Cossa and Guiseppe La Valle.—On the observations of atmospheric electricity made at the Central Meteorological Office, Rome, by Pietro Tacchini. Meteorological observations made at the Observatory of the Campidoglio during the month of May.

June 15.—Description of a Buddhist Codex in the Pali language, forwarded to the Academy by L. Nocentini, Italian Vice-Consul at Shanghai.—Obituary notice of Hermann Ulrici, by S. Ferri.—Reports on the influence of heat and magnetism on the electric resistance of bismuth, by Prof. Augusto Righi; on the constants of refraction, by Dr. R. Nasini; on the capillary equivalents of simple bodies, by Prof. R. Schiff.—Note on a problem in electrostatics, by Vito Volterra.—A method of determining the ohm in absolute measure, by Guglielmo Mengarini.—Experimental researches on the variation in the density of water between 0° and 10°, by Filippo Bonetti.—On the spectrum of absorption of the vapour of iodine, by Arnolfo Morghen.—Remarks on Shelford Bidwell's new explanation of Hall's phenomenon, by Augusto Righi.—On the electric conductivity of the combinations of carbon, by Adolfo Bartoli.—On the penetrability of glass by gases under pressure, by Adolfo Bartoli.—On the coexistence of different empirical formulas, and especially on those containing the capillary constant of liquids or the cohesion of solids, by Adolfo Bartoli.—On the atmospheric waves produced by the Krakatoa eruption, and observed at Palermo, by Gaetano Cacciatore.—Remarks on the dynamics of storms, by Ciro Ferrari.—On the intestinal canals and branchial tubes of the Salpidæ, by Francesco Todaro.—Report on the antiquities found in various parts of Italy during the month of May, by S. Fiorelli.

Revue d'Anthropologie, tome viii., fasc. 3, Paris, 1884.—The contents are:—An unfinished paper of Paul Broca, on his mode of preparing the cerebral hemispheres, which, with another chapter on the best methods of casting the required moulds, was to have formed part of the treatise on the circonvolutions of the [illegible]ematic brain, on which he was engaged at the time of his [illegible]th. The present paper breaks off in the middle of his exnation of the process of mummifying the brain.—An essay the ethnology of North Africa, by M. Camille Sabatier. [illegible] paper is entirely devoted to the consideration and recapitulation of the geographical descriptions given by Herodotus, Sallust, and other ancient writers of Lybia, under which designation most of the then known African continent was included. It also treats of the great invasions from Asia, and of the differences between the various African races. As distinct from the Lybians or mountaineers, and the Getulæ or pastoral occupants of the plains, the author believes we may recognise a separate branch, which bore the name of Escs or Oscs, and which probably have given origin to the modern Basque Escualdunacs and other kindred western races.—A continuation of M. Deniker's observations on the Kalmuks. This paper is devoted specially to the sociology of the people, the condition of the women, and the practices observed at betrothals, marriages, &c., being fully treated of. The Lamas, who exercise a great influence on the people—intervening in all the great events of life from the cradle to the grave—are employed in several of the steppes by the Russian Government to keep the civil registers of the various hordes. On various skulls of Arizona and New Mexico, by M. Ten Kate. From a comparative study of these and other crania collected by the author in his extensive travels in the Far West and in the Mexican territories, he is inclined to regard the constructors of the *casas grandes* of Arizona and the "cliff-dwellers" as closely allied to the Indian tribes of the Pueblos, or so-called "towns" of New Mexico. He found the same brachycephalic characteristics and the same evidence of artificial deformity in skulls of the ancient Pueblos of Quarra as in the modern Mexican Indians.—On the circumference of the thorax, and its relation to the dimensions of the rest of the body, by M. Ed. Goldstein. This paper is based on the data supplied by Dr. Snigerev in his great work on the recruiting of the Russian army, more especially in the districts of the Vistula and the north west of the empire. The great ethnological fact established by these determinations appears to be that, as compared with Poles, Germans, Lithuanians, Russians, and Samogitians, the Jews are distinguished by relative smallness of stature, and by the generally inferior dimensions of the chest, in both of which particulars they would appear to fall considerably below the mean of all the other races brought under the notice of the authorities at the head of the department for recruiting the Russian army.

Rendiconti del Reale Istituto Lombardo, July 17.—Note on the present conditions of the agricultural interests in Europe and America (continued), by Prof. Gaetano Cantoni.—Memoir on cellules and parasites in their pathological relations (concluded), by Prof. G. Sangalli.—Mental affection of Torquato Tasso; his detention in the Hospital of Sant' Anna, according to some recently-discovered documents, by Prof. A. Corradi.—On the equilibrium of elastic and rigid surfaces, by Dr. Gian Antonio Maggi.

SOCIETIES AND ACADEMIES

EDINBURGH

Royal Society, July 21.—The Right Hon. Lord Moncreiff, President, in the chair.—Mr. John Murray communicated, with remarks, a paper by Dr. Guppy of H.M.S. *Lark*, on the coral reefs and calcareous formations of the Solomon Group Islands. Dr. Guppy showed that the coral rocks were merely superficial, thus confirming Mr. Murray's theory that coral atolls and barrier reefs were formed without subsidence. A chalk, like the white chalk of England, had been discovered on one of the islands.—Prof. Tait gave an approximate empirical formula representing, for certain ranges, the compressibility of water in terms of the temperature and pressure.—Mr. J. T. Cunningham read a critical note on the latest theory in vertebrate morphology.—Mr. Milne Home submitted the tenth and final report of the Boulder Committee. At some period, geologically recent in the earth's history, an Arctic climate prevailed in the part of Northern Europe considered. As an effect, local glaciers occurred in Scotland, of some of which there were traces still visible. Subsequently Scotland was entirely submerged beneath the sea, and most of the valleys were filled with sand, gravel, and mud. A north-westerly oceanic current prevailed, carrying masses of floating ice with boulders, which were deposited on the hills.—Mr. H. R. Mill gave a paper on the periodic variation of temperature in tidal basins.—Mr. W. Peddie gave a communication on the isothermals and adiabatics of water near the maximum density point.—The meeting, which was the last for the session, was brought to a close by remarks from the Chairman on the work of the past session.

Sydney

Linnean Society of New South Wales, June 25.—The vice-president, Dr. James C. Cox, F.L.S., &c., in the chair.—The following papers were read:—Occasional notes on plants indigenous in the immediate neighbourhood of Sydney, No. 7, by E. Haviland.—On the new Australian fishes in the Queensland Museum, Part II., by Charles W. De Vis, M.A.—Sixteen species are here described, viz.:—Seven of the family Squamipinnes, two of the Mullidæ, one of the Sparidæ, four of Scorpænidæ, and two of the Teuthididæ.—On a marine species of *Philongria*, by Charles Chilton, M.A. The Isopod described in this paper was obtained at Coogee Bay last December. The specific name "*marina*" is given to it, as it is the only marine species of the genus known to the author.—The Australian Hydromedusæ (continued), Part iv., by R. von Lendenfeld, Ph.D. In this paper the numerous Australian species of Graptolithes, described by Prof. McCoy, of Plumularidæ described by Allman, Bale, Kirchenpauer and Busk, and of the Dicoryuidæ, are sifted and catalogued with references, and a large number of new and interesting species, and one new genus discovered by the author are described and figured. The Australian Plumularidæ exceed in the number of species the Plumularidæ of all the rest of the world put together.—On the flesh spicules of certain sponges, by R. von Lendenfeld, Ph.D. In a former paper the author expressed his opinion that flesh-spicules in sponges do not, as it was hitherto supposed, only occur in such species as possess a fibreous siliceous skeleton, but that they may make their appearance in any species, so that their existence cannot be considered of sufficient import to allow of a separate family being formed, comprising such sponges only which possess flesh-spicules. The author had based this hypothesis partly on general conclusions and partly on the observation of a true horn-sponge, a *Hircinia*, with flesh-spicules. Now the author is enabled to prove his hypothesis by further discoveries, which he made during the investigation of the numerous and valuable sponges of Port Jackson. He found, namely, three species possessing flesh-spicules, which, according to the structure of their fibrous skeleton, should be placed in the families of the horn-sponges.—Note on the slimy coating of certain Boltenias in Port Jackson, by R. von Lendenfeld, Ph.D. Some solitary Ascidians, similar to the ordinary *Boltenia australis*, which grows close to low tide mark, but which are found in deep water exclusively, are covered with a very slippery slime, an occurrence without precedence in Ascidians. This slime was investigated by the author, and found to consist of a thick layer of ova in their follicula-capsules. The slime is supposed to be formed by the cylindrical cells of the Folliculæ.—Report on the Australian Echinodermata exhibited at the Fisheries Exhibition, London, by F. Jeffery Bell, M.A., &c. This paper was communicated and read by E. P. Ramsay, F.L.S., &c. It contains a list of all the named species in the collection sent to London, viz. 10 species of the class *Crinoidea*, 12 of the *Asteroidea*, 19 of the *Ophiurioidea*, and 30 of the *Echinioidea*, with critical notes, &c.—Mr. Macleay exhibited for Mr. Wilkinson a very peculiar conical stone implement, found by Mr. A. G. Brook of Gondoblui Station, embedded in the soil on the plains near the Queensland border, between the Narran and Barwon Rivers. The note accompanying the exhibit states that there are no rocks near that locality, and that the old aboriginals of the district know nothing about it. The stone is composed of a soft, fine, white sandstone, is of conical form, nineteen inches in length and four inches in diameter in the middle: the surface presents a smooth, worn appearance. Dr. Cox suggested that it had probably been used for grinding nardoo, and that view seemed to receive most favour, though a number of different opinions were expressed. Mr. Macleay also exhibited for Mr. Wilkinson a number of helix-like shells, wound spirally round the leaf-stalks of a species of Eucalyptus, at Branxton on the Hunter. These shells, though calcareous, were pronounced not to be the production of any molluscous animal, and the general opinion was that they must be egg cases of some insect.—A large collection of shells and echinodermata from Cossack, Western Australia, sent by Mr. J. F. Bailey of Melbourne for exhibition, were on the table. Among the rarities *Conus trigonus* (Reeve), *Conus Victoriæ* (Reeve), *Ancillaria cingulata* (Sowb.), *Ancillaria elongata* (Gray), *Oliva Caldania* (Duclos), *Spondylus Wrightianus* (Cross).

Paris

Academy of Sciences, August 11.—M. Rolland, President, in the chair.—Note on the disposition of the fœtal envelopes in the aye-aye (*Chiromys madagascariensis*), by M. Alphonse Milne-Edwards. The author finds that there is nothing abnormal in the fœtal membranes of the aye-aye, and that they correspond in every respect with those of the typical lemurians, with which they must be definitely classified.—Observations in connection with a recent communication of General Menabrea on Charles Babbage's analytical calculating-machine, by M. Léon Lalanne. From an interview with Mr. Babbage at London in 1851 the author is led to believe that a document is still in existence either among the papers of M. Binet or among those of Mr. Babbage himself, in which he gives his final views on the subject of calculating-machines in general. M. Lalanne here publishes two original letters of Mr. Babbage referring to that document, and dated June 19, 1851.—Examination of two theorems connected with the rule of Newton; conclusions, by M. E. de Jonquières.—Remarks on the volcanic debris collected on the east coast of the island of Mayotte, at the north-west end of Madagascar, by M. E. de Jonquières. These debris, which were thrown up in considerable quantities on May 16, 1884, consisted of fine pumice, probably from Krakatoa. Amongst them was a large specimen already incrusted with shells. They appear to have traversed a distance of about 3840 nautical miles in 259 days at a mean velocity of 14·8 miles a day.—Note on the phenomenon of globular electric bolts, two illustrations, by M. Gaston Planté. The author produces artificially effects analogous to those of the fire-balls so often witnessed in the atmosphere.—Researches on some combinations formed by haloid salts with the oxygenated salts of the same metal, by M. H. de Chatelier.—Note on the influence of heat on the respiratory organs, by M. Ch. Richet.—Note on the influence of intellectual work on the elimination of phosphoric acid by the urine, by M. A. Mairet.—Anatomy of the maxillary apparatus in the locust, grasshopper, cricket, and other members of the family of grinding insects, by M. J. Chatin.—Contributions to the history of the Pliocene flora of Java, by M. L. Crié.—On some peculiar luminous phenomena observed about the sun at Morges, on the Lake of Geneva, by M. F. A. Forel.—Notes were received from M. Ch. W. Zenger on the possible existence of still undiscovered planetary bodies; from M. L. Jaubert on an aërolite seen on July 10; and from M. L. Favre on a classification of the sciences.

THE "ENCYCLOPÆDIA BRITANNICA"

The Encyclopædia Britannica. Ninth Edition. Vol. XVII. Mot-Orm. (Edinburgh: A. and C. Black, 1884.)

THE present volume of the "Britannica" contains an unusual number of articles of moderate length but of great importance. Among them are numerous articles of scientific interest, and of these we note especially the following:—

The article *Optics*, by Lord Rayleigh, is so good that it is to be regretted that considerations of space had to be attended to. The subject is one which has hitherto been presented in a form somewhat repulsive to the student; and the writer, who has contrived to make even *Primary and Secondary Focal Lines* attractive as well as interesting, deserves high credit. The general subject of Geometrical Optics had already been sketched in the article *Light*, so that the present article deals, almost exclusively, with the second (and sometimes higher) approximations. But Lord Rayleigh has not confined himself to the postulates of that science; he has freely availed himself of the principles of the wave-theory, whenever they were required to simplify a demonstration or to explain a result. And he intersperses, here and there, hints as to the easier methods of exhibiting and testing the results of theory, hints which will be of great advantage to the student.

Commencing with the theorem that a set of rays, originally perpendicular to a surface, can, after any number of reflections and ordinary refractions, be cut orthogonally by another surface, the author develops generally the properties of Caustics and Focal Lines. He then proceeds to apply these properties to prisms, mirrors, and lenses. The practical adjustment of the collimating and observing telescopes for spectroscopic work, and the accurate measurement of refractive indices are described. Here we have some interesting remarks on the reasons for employing the position of minimum deviation in the observation of spectral lines. Next we have the formation of a pure spectrum, specially for the purpose of securing a visual field uniformly illuminated with homogeneous light. This leads to a general sketch of the methods and results of von Helmholtz and Clerk-Maxwell with regard to compound colours. Then we have a discussion of Spherical and Chromatic Aberration, with some brief but highly practical remarks on the construction of achromatic and aplanatic lenses for different purposes. Stokes' important results as to the secondary spectrum are here given with some detail; and the methods of Foucault and Töppler for detecting slight defects of figure, or slight irregularities of refractive index, are explained. Next come the important questions of the brightness of an image, and the *resolving power* of an optical instrument. The limits to resolving power, with the important difference, in this respect, between the telescope and the microscope, are well, but only too briefly, given:—and we have also a short *résumé* of the author's own important discussion of the same question for spectroscopes and gratings. We conclude with the remark, which has been forced on us at almost every paragraph, that while brevity is often a most desirable virtue, it is one whose exercise should be permitted only to those (no doubt the majority) who have nothing to say. Lord Rayleigh would do a great service to science if, taking the present essay as a skeleton, he would develop it into a handy volume.

Prof. Cayley handles the subject of Numbers, from the mathematician's point of view, in two compact articles. That on the *Partition of Numbers*, which is little more than explanatory of the term, we pass over. That on the *Theory of Numbers* is a very carefully written account of the past condition and present position of a subject, "which, originating with Euclid, has in modern times, in the hands of Legendre, Gauss, Lejeune-Dirichlet, Kummer, Kronecker, and others [we may interpolate the names of Cayley, Sylvester, and Henry Smith], been developed into a most extensive and interesting branch of mathematics." The branch is well known to be one of limited interest, for does not De Morgan write that the subject is an isolated part of mathematics, which may be taken up or not at the choice of the student? 'It may possibly at some future time be connected with ordinary analysis; that is to say, the determination of the *integer* solutions of a set of equations may not be so distinct a thing from that of a mere solution, integer or not, as it is at present." The author distinguishes between the ordinary (or simplex) theory and the various complex theories. "In any theory, ordinary or complex, we have a first part, which has been termed the theory of congruences; a second part, the theory of homogeneous forms; and a third part, comprising those miscellaneous investigations which do not come properly under either of the foregoing heads." The details are too technical for these columns, but the *résumé* of results is drawn up in a manner likely to be most useful to a student, as it clearly indicates the present condition of matters, being brought down to the very latest date by a master who has done good work in this very direction. There are a few typographical inaccuracies; besides we note the following trifling (we think) oversights:—In Article 15 it is said: "If p is not a prime number, then $1, 2, 3 \ldots (p-1) \equiv 0$ (mod. p),"—surely it should be added, "except when $p = 4$"; in Art. 16, line 13, last bracket, for $x - 3$ read $x - 4$; in Art. 19, lines 9, 10, interchange 11 and 17; in Art. 20, line 15, should not 13 and 35 be relegated to the next line? The whole article is so carefully printed that we have thought it not out of place to point out these oversights.

Capt. Moriarty's reputation as a practical navigator has given an unusual interest to the article on *Navigation*, in which he may have been expected to impart to others the trick of his own skill. We must confess to a certain amount of disappointment. The essay is well enough, but it is not what we expected; not what, we still think, we had a right to expect. It is in fact little more than a short elementary treatise on the subject, comprising some of the simpler and more familiar problems, but taking little note of the more exact or more convenient methods which are often required, not perhaps for the daily determination of a ship's position at sea, but for the checking

of the chronometers and compasses, or for the more certain guidance of the vessel when in with the land. And for an account of such the "Encyclopædia" is, we conceive, the proper place: for it is not a work addressed to a youngster learning for the first time how to rough out a course and distance, or to work a meridian altitude or chronometer; but rather to the general reader wishing to gain some insight into the methods in use, or to the adept who is desirous of a ready reference to those branches of the subject which do not come within the scope of the ordinary text-books.

It is thus that we do not agree with Capt. Moriarty in the disparagement of lunars, which he would relegate altogether to the examination room; the excellence of chronometers in the present day renders—he seems to say—lunars of no practical use; and holding this opinion, his notice of the problem is incomplete, and certainly very unpractical. But Sir Charles Shadwell, whose scientific knowledge of the subject is at least equal to that of Capt. Moriarty, has within these last three years pointed out ("Notes on the Reduction of Lunar Observations," Potter, 1881) that the lunar method is the only one which gives the seaman an independent astronomical solution of the problem of finding longitude at sea. "Chronometers," he says, "may fail, or go astray; accident or carelessness may neglect to wind them up; errors may have been committed in determining or applying their rates, which may not have been discovered till too late to rectify them. In these dilemmas, the sole remedy available for pointing out the real position of the ship in longitude, is a lunar observation." Capt. Moriarty presumably thinks that the rarity of such "dilemmas" renders them of no practical importance: that they do occur, however, is within the cognisance of every navigator; but we fear that under the influence of teaching such as this, the skill to get out of the dilemma in a masterly manner is rapidly becoming scarce: for, as Sir Charles Shadwell has well said, "Confidence in the hour of uncertainty cannot be improvised for the occasion; it can only be the result of habitual practice." We venture therefore to protest most earnestly against the pernicious doctrine to which Capt. Moriarty has lent the sanction of his name. If it is worth a ship's while to carry the cumbrous and costly array of masts and rigging as a stand-by in the event of the huge and powerful engines being disabled, it is surely at least equally worth while to carry the handy and inexpensive skill to observe and compute a lunar, as a check on the very delicate machinery of a chronometer.

In speaking of these, the most exact of all observations with the sextant, we may call attention to the very insidious error which arises from false centering, and which is much more common than is generally understood. To detect this and find the corrections for it, Capt. Moriarty recommends the taking and computing a number of equal altitudes, comparing the error of chronometer so found with the known error of chronometer. This method is excessively laborious, but may be shortened somewhat by the construction of a curve of error, as Capt. Moriarty has described. There is also the danger, which he has omitted to notice, of the whole work going round in a vicious circle; of first determining the error of chronometer by a faulty sextant, and of then using that error to correct the sextant. Capt. Moriarty appears not to know, or has at any rate neglected to point out, that, for an almost nominal fee, sextants can be tested at Kew by a specially constructed apparatus, the invention (we believe) of Mr. Francis Galton. Many men buy a sextant with as little care as they would buy a gridiron; but no one who means to use his sextant for purposes of exact navigation should think of concluding the purchase without getting a satisfactory Kew certificate with it. If he does, he richly deserves all the trouble and annoyance which the neglect of this very simple precaution may entail.

Perhaps the best section of Capt. Moriarty's article is that in which he has treated of the modern application of what is commonly known as Sumner's method of determining a ship's position; what he says on this subject is admirable; we can only wish that he had devoted a little more space to it, and given it a full development; for the theory and the practical use of lines of equal altitude are, as yet, neither sufficiently understood nor attended to by navigators. It would, for instance, have been well to have called attention to the very exceptional value of Venus for these observations; and to the many special cases which arise when the bearing of a distant peak can be taken. In conclusion, we would heartily endorse Capt. Moriarty's commendation of Raper's "Practice of Navigation." It is, beyond question, the best practical work which has yet appeared, and we cannot but express our regret that neither in the Royal Navy nor in the Merchant Service, are its merits properly recognised. The text-book commonly used in the Navy is Inman's, as edited by Jeans; that used in the Mercantile Marine is Norie's. Either of them is very far inferior, as a practical work, to Raper; but the difficulty of changing an established text-book has hitherto been found insuperable.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Electric Light for Lighthouses

In your interesting article on the experiments on lighthouse illumination now in progress at the South Foreland (p. 362) the writer alludes to the remarkable quenching influence of even a light mist on the electric light as compared with either gas or oil lights, and suggests that the smaller area of the illuminating centre in the case of electricity may have something to do with the matter.

Apart from this, however, selective absorption by water vapour must play an important part, and a great deal must depend on the colour of the beam; that is to say, the proportion of different rays combined in it.

MM. Janssen, Ångström, and others have shown that vapour of water in the atmosphere reduces the intensity of the violet end of the spectrum in a general manner and the red end in a more special manner. An examination of Ångström's map of the telluric lines in the solar spectrum (see Schellen's "Spectrum Analysis," Huggins' translation, Fig. 95, p. 264) will show that, while the extreme red and all the blue ends of the spectrum are much darkened by absorption lines, there is a zone from between B and C to δ which is comparatively free from them. This region includes the orange rays, and part of the red and yellow. It is the most luminous part of the spectrum, and contains the rays which will penetrate farthest in a fog. Hence it is that the

sun appears redder as it sinks towards the horizon, and loses more of its blue rays in the thicker atmosphere.

Gas and oil lights are richer in these penetrative rays than the arc light, which is peculiarly rich in the blue rays easily absorbed. Hence a gas jet can be seen a long distance in a fog, though, like the sun, it appears redder in tinge than usual. An arc light, on the other hand, is not seen far, however penetrative it may be in clear weather. I have often observed on London Bridge, in a fog, that the arc lamps become of a blank white; the brilliant arc seems to disappear, and the carbon points, slightly reddened, glow through the mist. The arc with its blue rays is the part which suffers most, and hence the larger the incandescent points in comparison, the likelier the light to penetrate. The ordinary electric incandescent lamp has, according to the late R. Sabine, 20 per cent. more orange rays than daylight, a fact which may account for its greater penetrative power than the arc; but, owing to its cost, it is debarred from lighthouse work.

On the whole it would appear advisable to employ the spectroscope in the South Foreland experiments, in order to find out what the absorptive action of mists is on arc, gas, and oil lights. If it should turn out, as above indicated, that the arc fails in penetration from lack of certain yellow, orange, and red rays, it might be useful to try the effect of supplying the needful rays by mixing certain salts with the carbons. The Cholera Germ

THE importance of our gaining clear ideas of the cause of cholera as soon as possible prompts me to venture to suggest the direction in which may be sought an explanation of the three propositions in NATURE (p. 26), and which "E. K." there says "appear to me to be in hopeless contradiction." The propositions are, substantially, as follows:—(1) The comma-shaped bacillus is the cause of cholera; (2) the alimentary canal is the exclusive organ of its entrance into the body; (3) the comma-shaped bacillus is killed by acid.

The life of most plants is destroyed by passing through the alimentary canal of animals or man, yet seeds of grasses, grains of cereals, &c., not infrequently pass through animals without destruction, and afterwards germinate and reproduce their kind. Seeds of small fruits sometimes pass uninjured through the human body and through birds. Spores of bacilli are known to withstand treatment which is destructive of the bacilli themselves. Unless the comma shaped bacillus is exceptional in not forming such spores, it seems to me that the three foregoing propositions may not only be thus explained, but that they may soon supply an explanation of what has been long waiting explanation, namely, the fact that the dejections of cholera patients are not often, if ever, found infectious when first voided, but soon become infectious. This accords perfectly with the three propositions if we suppose that the comma-shaped bacillus, soon after being voided in the dejections, forms spores which are capable of resisting the acids of the stomach. It seems very important to have this point investigated. To plead for such investigation, by whoever has opportunity, is a main object of this letter.

The many instances of the outbreak of cholera in this country (U.S.A.) immediately after infected baggage has been unpacked, might then receive easy explanation; the spores, being inhaled with the breath, would be likely to lodge in the posterior nares and pharynx, be swallowed, passed through the stomach, and in the nutritive alkaline fluids of the intestines find a congenial soil in which to germinate, forming comma-shaped bacilli giving off their poisonous by-product which seems to have such baneful influence on the human nervous system.

Lansing, Michigan, August 8 HENRY B. BAKER

School Museums

DR. GLADSTONE does not allude to botanical specimens in his communication to NATURE last week (p. 384), but these can form a very interesting addition. In my father's parish school of Hitcham, he had a long row of phials fixed against the wall of the class-room, with the name of every plant of the parish attached below. These were kept constantly supplied by the children all through the summer. Whoever first brought any species had a small reward. The School Herbarium was entirely made by the children; and for the last twenty-five years I have used for teaching purposes specimens dried, mounted, and labelled by the children of Hitcham School. Should any one desire further details on the subject of botany in schools, I shall be very glad to communicate with such.

Drayton House, Ealing GEORGE HENSLOW

THE circulating loan collections of natural history specimens, referred to by Dr. Gladstone in his letter on this subject as being established at Liverpool, have been provided and organised not by the School Board but by the Free Library and Museum Committee of the Corporation. They owe their origin almost entirely to the Rev. H. H. Higgins, chairman of the Museum Sub-Committee, and their great value is due to the close personal attention which that gentleman and the Curator of the Museum (Mr. T. J. Moore) have bestowed on them. The specimens included in the collections are not only typical, but are of excellent quality, and cannot fail to arouse the interest of the children before whom they are brought. So far as the experiment has already gone it has proved very successful, and deserves to be widely known.

Having had the pleasure of bringing the matter of these collections forward in the discussion on Dr. Jex-Blake's paper at the Educational Conference, I should be glad if you would allow me to make this correction as to their origin.

21, Verulam Street, Liverpool, Aug. 25 W. HEWITT

The Permanency of Continents

As a small contribution to this theory, the Cornish beaches may furnish a quota. They are entirely composed of finely comminuted shells, with a small admixture of fragments of Bryozoa, spines of minute Echinoderms, and occasional mica flakes. Such sandy beaches occur in small bays, and if subjected to metamorphic action would form *lenticular masses of limestone* intercalated between the strata deposited above and below them. Hence such occurrences of limestone might well indicate such a *littoral* origin as is here displayed.

St. Ives GEORGE HENSLOW

Carnivorous Wasps

I ONCE witnessed a somewhat similar feat to that mentioned by "F. N." (p. 385). It was at a wayside inn in the Eifel. The tablecloth was covered with flies. The window was closed excepting one small corner at the top. A wasp entered, came direct to the table, but instead of attacking some stewed fruit thereupon, instantly seized a fly, bore it off, and after whirling round with it, made straight for the small means of exit and vanished.

One evening when at College a small beetle was flying round and round, but at some height over the lamp. A spider on the ceiling watching his opportunity, suddenly dropped upon it and *caught it flying!* He then ran up with it and began winding a belt of silk round its body. However the beetle ultimately managed to slip its meshes and escaped.

GEORGE HENSLOW

IN reply to your correspondent "F. N.," I would say that, while I do not recollect to have seen wasps, under natural conditions and in the open air, attacking flies, I have frequently seen a wasp, when shut up in a room, or supposing himself to be so (for wasps are very stupid in finding their way out of a room), attack and partially devour the common house-fly. I yesterday witnessed an instance of cannibalism on the part of the wasp. One of my drawing-room windows was closed, and on this seven or eight wasps were engaged in a fruitless struggle against the irritating and inexplicable glass, instead of escaping, as they might have done, through the other windows, which were open. One of them, more languid and weary than the rest, was crawling slowly up and down near the corner of the pane. Some minutes afterwards, looking up from my book, I noticed two of the other wasps engaged in furiously attacking this individual. After a few seconds, one of the opponents, perhaps endowed with higher moral susceptibilities than the other, flew away. The other seized upon the thorax of the now moribund wasp, and, after a few moments, began devouring him. I watched the process for a minute or two, and then the cover of a book put an end to the existence of the cannibal and of his prey.

A day without food reduces a wasp to a state of famine, and it might be easily ascertained whether he does not commonly,

like animals of a higher order, become a cannibal under these circumstances. W. CLEMENT LEY

Lutterworth, August 22

I HAVE twice within the last few days noticed the same thing that your correspondent writes about, viz. wasps devouring flies. In the first instance the fly was found held fast by the feet of a wasp which I had killed; the fly was dead, but I think intact. In the second instance the body of the fly was reduced to a shapeless mass, and about half had been devoured, no doubt by the wasp. I had previously observed a wasp apparently attacking a butterfly (small white), possibly for the same purpose; it was, however, unsuccessful. I do not know whether it is unusual for wasps to do this, but I have certainly never observed it before. H. N. DIXON

Northampton

THE question of your correspondent "F. N." in your last number (p. 385), inquiring whether the incident observed by him is an unusual occurrence or not, is one that has been so frequently asked that it is somewhat curious that the fact has not become recognised generally as constituting a regular habit of the insect. Four years ago several letters upon this subject were communicated to NATURE (*vide* vol. xxi. pp. 417, 494, 538, 563, and vol. xxii. p. 31), and many other notices of the practice might be quoted. Darwin related having observed a wasp seize and carry off a fly too large for convenient transport, which returned to the ground to cut off the wings to lighten its weight, and then flew away with it. During the hot months, butchers' shops, as I have frequently noticed, are much resorted to by wasps as a hunting-ground, and although they are also fond of the juice of dead meat, they are encouraged rather than destroyed, in consequence of the benefit they confer by their habit of preying upon "blow-flies," as I have more than once been told by the shopkeepers themselves. WILLIAM WHITE

Highbury Hill, N., August 23

WITH reference to the account of the wasp and fly in NATURE by "F. N.", though not exactly an answer to the query put, still the following may be of some interest to him and others of your readers:—

I was sitting one day in an arbour in the grounds of Duff House, when a wasp and a bluebottle-fly fell at my feet. Here a scuffle (it could scarcely be called a fight) ensued, which lasted a few seconds. I think the wasp used its sting as well as its mandibles. The fly dead, the wasp then tried to lift it. This was frequently repeated, but without avail. The wasp then went round and round and over the fly several times. Then another trial. But no; it seemed to me that the fly was too heavy or too bulky. The wasp now began to nibble at the body of its prostrate victim, and at last severed it in two. It then seized one portion, and after making the attempt twice, succeeded, rose, and disappeared. In a little while, however, I was rather surprised to see the wasp return; at least one similar came, and having whizzed round about my head, looked at me, went and hovered for an instant or so above the spot where the other half of the fly lay, then alighted, and bore it off in triumph. I do not think that the wasp intended to eat the fly, but rather meant it as food for the larvæ at home. THOMAS EDWARD

Banff, Scotland

SEEING the communication of "F. N." on a "Carnivorous Wasp" in last week's NATURE brings to my recollection a similar observation of my own about a fortnight ago. My attention was drawn to an immense number of wasps and flies feeding together, apparently in perfect amity, at the bottom of a recently emptied sugar hogshead that was lying on its side in the sun. The amity, I may say, was not altogether perfect, as when a wasp approached a fly the latter speedily gave way. Suddenly a wasp, which was flying about in the interior of the tub, darted on an unsuspecting fly which was peacefully regaling itself with sweets, and carried it off. I managed to trace its flight to a neighbouring wall, where I saw the wasp apparently busily engaged in devouring the fly. On approaching more closely, in order to find out if I could what these unamiable proceedings were, I disturbed the wasp, which flew away with the fly still in its grasp, and this time I was unable to follow it. My impression at the time was, I remember, that the wasp wished to rob the fly of its sugar. This was the only case I noticed.

Leicester, August 25 E. F. BATES

[We have received numerous letters of the same purport as the above. The subject was discussed in NATURE, vols. xxi. and xxii., as referred to by Mr. White above.—ED.]

Fireballs

WHILST speaking of the electric discharge to the Rev. Canon Thomas, of Meifod, a few days ago, he told me that he was some years ago overtaken by a most violent storm of thunder and lightning whilst crossing on horseback a Merionethshire mountain. During this storm Mr. Thomas saw (what appeared to him to be) three balls of fire successively hurled to the ground near him from the clouds.

About a fortnight ago a sudden and violent thunderstorm broke over North-East London, when at least one building was struck. The window of my room was wide open at the top. During one of the peals of thunder a zigzag line of lightning was distinctly seen by me (and another person) to come into the room by the open window and form an irregular line of fire along the cornice of the room. In the middle of the zigzag there seemed to be a momentary stoppage, with a star-like expansion of the line. There was no reflection or optical illusion, and no damage was done. W. G. SMITH

A Cannibal Snake

I SEND the following brief history of a snake's meal off another about his equal in bulk.

Some years since I was amused at the conduct of a small triangular-headed snake about ten inches long that I encountered in a road, who coiled himself and struck at me as if to dispute my progress. He was a pretty little fellow, gray spotted, and I picked him up, and carrying him home, deposited him in a small fish globe with sand and stones in the bottom. Here he lived contentedly for several months without eating anything, although frequently tempted with various insects and other food. After three months or so, my neighbour's children brought in a small black snake, shorter, but rather larger in diameter than my pet, and we decided to place the two together. Scarcely had the new-comer touched the sand than my pet glided rapidly around the sides of the globe, and struck him with his fangs just behind the head. The black snake dropped apparently lifeless, the other retained his hold with his jaws, and winding his tail closely about midway up the body, stretched himself out and his prey at the same time, till he seemed to dislocate his vertebra. We could hear the black snake crack. An hour or so later I found that he had begun to swallow him, having already got the head fairly inside his jaws. I called my family and neighbours, and we watched the process for several hours. He coiled the lower part of his body around his prey at the distance of an inch or two from his jaws, so tightly that it seemed almost to cut it in two, and then appeared to curl himself together and force the portion between the coil and his jaw down his throat. When that portion was ingested, he took a fresh hold lower down and repeated the action. The black snake disappeared quite rapidly, until the amount swallowed distended and stiffened the other, so that he could not hold it with a coil. After this the process was slow and tedious, apparently being mainly carried on by alternate retractions of the jaws, and it took nearly half an hour to dispose of the last inch, which was of course very small. Finally he succeeded, and lay stretched out, a singular-looking specimen, his outline distorted by the convolutions of the reptile he had swallowed, which could plainly be traced through his distended skin. He lay quiet for several days, and apparently digested the greater portion of it. I never fed him again, and finally turned him loose, his parting salute being a vicious attack upon my boot. C. F. CREHORE

Newton, Massachusetts, August 12

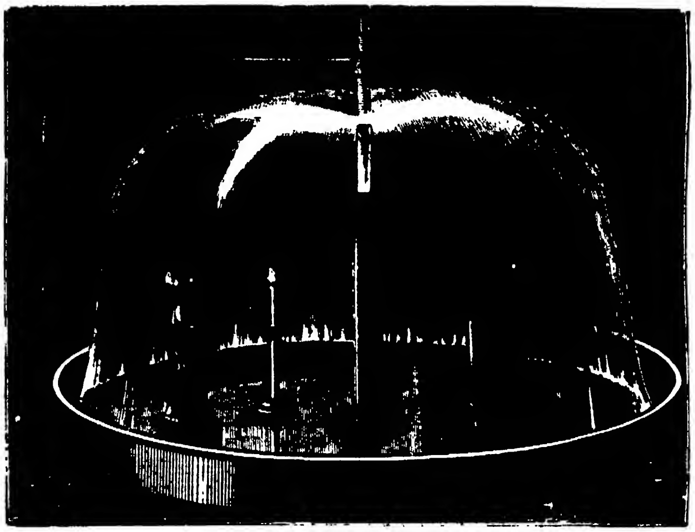
WATER BELLS

THE accompanying design (from *La Nature*) represents a water bell, the invention of M. Bourdon, of more transparent and complete effect than those hitherto produced, which have all either made the water issue by a very diminutive annular orifice, or shot the liquid jet

against a disk of polished metal with slightly elliptic rim, producing in either case a bell fringed all round its circumference and lacking transparency.

The bell to which we here call attention is distinguished by the way in which it causes the liquid vein to expand as soon as it reaches the orifice of the ajutage. Instead of making it strike against a metal plate, the surface of which, however carefully polished, always betrays some imperfection, M. E. Bourdon brings an antagonistic column of water to bear on it, so that the jet expands and falls into the basin, forming a bell as clear as crystal and impervious enough to cut off all communication between the interior and circumambient air.

The pipe conducting the water from the reservoir ends in a truncated form of nozzle, of about 12 degrees of angular opening, in such a way as to make all the threads of water converge towards the middle of the jet. Over this is placed concentrically to the truncated nozzle a glass tube of about 20 cm. in length, and of the same interior diameter as that of the orifice by which the water rises from the reservoir. This antagonistic tube, as it may be called, has to be supported by a copper rod fixed either against a wall or on the margin of the basin, at a distance of 2 cm. between its lower extremity and the truncated appendage. The reservoir must be kept at a constant level by means of a water-gauge cock. The



water-height above the jet will be about 60 cm. The flow of the water or its stoppage will of course be regulated by a cock.

The apparatus so arranged and the basin filled with water to the level of the overflow, the cock will be gently opened, and the water traversing the interval between the ajutage and the antagonistic tube will rise a few centimetres high in the latter. A ball of ovoidal shape will then come to view. By opening the cock very slowly its diameter will gradually enlarge till the bell assumes the form of a hemisphere. At this point let the opening of the cock be reduced a very little, and the bell will change its shape; its rim will become lowered to the plane of the water of the basin, and its profile will show a bell similar to the gardener's bell glass.

By placing a very thin copper wire vertically towards the top of the bell, a vertical incision may be made in the bell, parting it into two separate sides. Through the gap thus formed, a statuette, a lighted candle, or a cage containing a bird, may be introduced inside the bell without wetting it. The tubes hitherto used have not exceeded 20 mm. in diameter; but by employing apparatus of much larger dimensions, water bells of from 3 to 4 metres in diameter might be produced just as perfect as those of from 60 to 80 centimetres, and under which people might walk about or lounge at pleasure.

SCIENCE AND THE SANDHURST EXAMINATIONS

WE have now before us the revised regulations for the examinations of candidates for admission to the Royal Military College, Sandhurst. Up to and including the summer examination of 1885 the present scheme is to remain in force. Under it Mathematics, English History, and Latin receive 3000 marks each; Greek, French, German, Experimental Science, General and Physical Geography and Geology count 2000 marks each. Candidates are left free to select *any* four of these subjects. They may also take up drawing, for which 1500 marks are given. After the summer of 1885 the subjects are to be grouped and marked as follows:—

		Marks
CLASS I.—	1. Mathematics	3000
	2. Latin	3000
	3. French	3000
	4. German	3000
CLASS II.—	1. Greek	2000
	2. Higher Mathematics	2000
	3. English History	2000
	4. Experimental Sciences ...	2000
	5. Physical Geography and Geology	2000
CLASS III.—	1. English Composition	500
	2. Drawing, Freehand	500
	3. ,, Geometrical	500

Of these subjects candidates *must* take up three from Class I., and may take up either the remaining subject in Class I. or any one subject in Class II., and may also take up all the subjects in Class III.

These figures speak for themselves. Science is now placed on an equal footing with Greek and Higher Mathematics, &c., and its position is therefore somewhat improved as compared with that assigned to it in the proposals of a few months since. In the main, however, the revised scheme cannot be satisfactory to any one who has the interests of education at heart.

After our article of June 26 (p. 189) it is needless to go much further into detail, but it may be pointed out that hitherto certain subjects, of which Science is one, have had 2000 marks each, whilst three others have had 3000, and free choice of four subjects among these has been allowed. Owing to the great influence which marks have naturally exercised upon the choice of candidates and to other circumstances, the position of Science has been modest enough. In future, however, it will have (to put it numerically) about one-fourth of its previous chance, since, instead of the candidates being free to select four subjects, they will now only be free to select one. In short the final arrangements, though undoubtedly improvements upon those announced a few months since, and in one particular considerable improvements, are in their main features retrograde and unsound. They will hamper those of our schools which make it their aim to widen the basis of education in this country by the introduction of science into their regular work, and they will further discourage those who have hitherto hesitated from following their example. They will be a check on freedom and progress in education. The new regulations no doubt will encourage the study of modern languages. They do this, however, at too great a cost to other subjects of at least equal importance. We regret very much that the War Office authorities have not adopted some plan by which, whilst securing a knowledge of those subjects which they regard as professionally essential, they would have left a fairer field to such studies as Higher Mathematics, Natural Science, Greek, &c. Whilst we regret so much the blow to science teaching in our schools which is given by the final adoption of the scheme before us, and that young men of scientific capacity should stand so poor a chance of employment in our military services, we must acknowledge that in their revised regulations the War Office authorities have effected a distinct improvement by the new grouping of the experimental sciences and the addition of a practical examination to each group; although, from the greatly inferior position which science will hold in future, we fear that the practical advantage in the Sandhurst examinations will be very small. If, however, such a grouping of the natural sciences could be extended to the Woolwich examination also, it would be a great gain. The allotment of marks at present in force in the Woolwich competitions deals very fairly with the various subjects. Mathematics and Drawing, which are of special importance, are duly encouraged, whilst a fair liberty of choice among other subjects is left to the candidates. It has, however, been a complaint that, owing to the unequal difficulties presented by the present groups, some science subjects are unduly encouraged at the cost of others. This complaint ought practically to cease under such a classification as is now introduced into the Sandhurst scheme, for it ought no longer to be difficult for the examiners to set papers of fairly equal difficulty and range. We hope this change of detail may be extended to the science of the Woolwich examinations. We believe it would be welcomed by all those who have the interests of science teaching at heart.

THE BRITISH ASSOCIATION

THE fifty-fourth annual meeting of the British Association commenced yesterday at Montreal. About 800 members have arrived in Montreal from England, and the interest taken in the meeting both in Canada and the United States is evidenced by the great number of visitors which it has attracted to that city. The reception accorded to the Association both by the city and the Dominion is all that could be wished. Montreal itself has raised a fund of 40,000 dollars for expenses, and over 300 members have been received as guests into private houses. McGill College, where the Association meets, has been specially prepared for the purpose, and there is every probability that the meeting will be a success in all respects.

The proceedings began last night with the address of the President, Lord Rayleigh, who was to be introduced by Sir William Thomson. To-day the Sectional proceedings began, and it will be seen from what follows that the addresses are quite up to the average. To-morrow evening Prof. Lodge delivers his lecture on "Dust"; on Saturday Prof. R. S. Ball gives the popular lecture, his subject being "Comets"; and on Monday evening Dr. Dallinger gives a richly illustrated account of the lowest forms of life.

Extensive arrangements have been made for excursions of the members to Quebec, Ottawa, and other places of interest in the Dominion and the United States, with garden parties, *soirées*, and receptions, in the intervals of the meetings. The citizens of Quebec are arranging to entertain 600 members on Saturday.

INAUGURAL ADDRESS BY THE RIGHT HON. LORD RAYLEIGH, M.A., D.C.L., F.R.S., F.R.A.S., F.R.G.S., PROFESSOR OF EXPERIMENTAL PHYSICS IN THE UNIVERSITY OF CAMBRIDGE, PRESIDENT

IT is no ordinary meeting of the British Association which I have now the honour of addressing. For more than fifty years the Association has held its autumn gathering in various towns of the United Kingdom, and within those limits there is, I suppose, no place of importance which we have not visited. And now, not satisfied with past successes, we are seeking new worlds to conquer. When it was first proposed to visit Canada, there were some who viewed the project with hesitation. For my own part, I never quite understood the grounds of their apprehension. Perhaps they feared the thin end of the wedge. When once the principle was admitted, there was no knowing to what it might lead. So rapid is the development of the British Empire, that the time might come when a visit to such out-of-the-way places as London or Manchester could no longer be claimed as a right, but only asked for as a concession to the susceptibilities of the English. But seriously, whatever objections may have at first been felt soon were outweighed by the consideration of the magnificent opportunities which your hospitality affords of extending the sphere of our influence and of becoming acquainted with a part of the Queen's dominion which, associated with splendid memories of the past, is advancing daily by leaps and bounds to a position of importance such as not long ago was scarcely dreamed of. For myself, I am not a stranger to your shores. I remember well the impression made upon me, seventeen years ago, by the wild rapids of the St. Lawrence, and the gloomy grandeur of the Saguenay. If anything impressed me more, it was the kindness with which I was received by yourselves, and which I doubt not will be again extended not merely to myself but to all the English members of the Association. I am confident that those who have made up their minds to cross the ocean will not repent their decision, and that, apart altogether from scientific interests, great advantage may be expected from this visit. We Englishmen ought to know more than we do of matters relating to the Colonies, and anything which tends to bring the various parts of the Empire into closer contact can hardly be over-valued. It is pleasant to think that this Association is the means of furthering an object which should be dear to the hearts of all of us; and I venture to say that a large proportion of the visitors to this country will be astonished by what they see, and will carry home an impression which time will not readily efface.

To be connected with this meeting is to me a great honour, but also a great responsibility. In one respect, especially, I feel that the Association might have done well to choose another President. My own tastes have led me to study mathematics and physics rather than geology and biology, to which naturally more attention turns in a new country, presenting as it does a fresh field for investigation. A chronicle of achievements in these departments by workers from among yourselves would have been suitable to the occasion, but could not come from me. If you would have preferred a different subject for this address, I hope at least that you will not hold me entirely responsible.

At annual gatherings like ours the pleasure with which friends meet friends again is sadly marred by the absence of those who can never more take their part in our proceedings. Last year my predecessor in this office had to lament the untimely loss of

Spottiswoode and Henry Smith, dear friends of many of us, and prominent members of our Association. And now, again, a well-known form is missing. For many years Sir W. Siemens has been a regular attendant at our meetings, and to few indeed have they been more indebted for success. Whatever the occasion, in his Presidential Address of two years ago, or in communications to the Physical and Mechanical Sections, he had always new and interesting ideas, put forward in language which a child could understand, so great a master was he of the art of lucid statement in his adopted tongue. Practice with Science was his motto. Deeply engaged in industry, and conversant all his life with engineering operations, his opinion was never that of a mere theorist. On the other hand, he abhorred rule of thumb, striving always to master the scientific principles which underlie rational design and invention.

It is not necessary that I should review in detail the work of Siemens. The part which he took, during recent years, in the development of the dynamo machine must be known to many of you. We owe to him the practical adoption of the method, first suggested by Wheatstone, of throwing into a shunt the coils of the field-magnets, by which a greatly improved steadiness of action is obtained. The same characteristics are observable throughout—a definite object in view and a well-directed perseverance in overcoming the difficulties by which the path is usually obstructed.

These are indeed the conditions of successful invention. The world knows little of such things, and regards the new machine or the new method as the immediate outcome of a happy idea. Probably, if the truth were known, we should see that, in nine cases out of ten, success depends as much upon good judgment and perseverance as upon fertility of imagination. The labours of our great inventors are not unappreciated, but I doubt whether we adequately realise the enormous obligations under which we lie. It is no exaggeration to say that the life of such a man as Siemens is spent in the public service; the advantages which he reaps for himself being as nothing in comparison with those which he confers upon the community at large.

As an example of this it will be sufficient to mention one of the most valuable achievements of his active life—his introduction, in conjunction with his brother, of the regenerative gas furnace, by which an immense economy of fuel (estimated at millions of tons annually) has been effected in the manufacture of steel and glass. The nature of this economy is easily explained. Whatever may be the work to be done by the burning of fuel, a certain *temperature* is necessary. For example, no amount of heat in the form of boiling water would be of any avail for the fusion of steel. When the products of combustion are cooled down to the point in question, the heat which they still contain is useless as regards the purpose in view. The importance of this consideration depends entirely upon the working temperature. If the object be the evaporation of water or the warming of a house, almost all the heat may be extracted from the fuel without special arrangements. But it is otherwise when the temperature required is not much below that of combustion itself, for then the escaping gases carry away with them the larger part of the whole heat developed. It was to meet this difficulty that the regenerative furnace was devised. The products of combustion, before dismissal into the chimney, are caused to pass through piles of loosely stacked fire-brick, to which they give up their heat. After a time the fire-brick, upon which the gases first impinge, becomes nearly as hot as the furnace itself. By suitable valves the burnt gases are then diverted through another stack of brickwork, which they heat up in like manner, while the heat stored up in the first stack is utilised to warm the unburnt gas and air on their way to the furnace. In this way almost all the heat developed at a high temperature during the combustion is made available for the work in hand.

As it is now several years since your presidential chair has been occupied by a professed physicist, it may naturally be expected that I should attempt some record of recent progress in that branch of science, if indeed such a term be applicable. For it is one of the difficulties of the task that subjects as distinct as mechanics, electricity, heat, optics, and acoustics, to say nothing of astronomy and meteorology, are included under physics. Any one of these may well occupy the life-long attention of a man of science, and to be thoroughly conversant with all of them is more than can be expected of any one individual, and is probably incompatible with the devotion of much time and energy to the actual advancement of knowledge. Not that I would complain of the association sanctioned by common parlance. A sound knowledge of at least the principles of general physics is necessary to the cultivation of any department. The predominance of the sense of sight as the medium of communication with the outer world, brings with it dependence upon the science of optics; and there is hardly a branch of science in which the effects of *temperature* have not (often without much success) to be reckoned with. Besides the neglected borderland between two branches of knowledge is often that which best repays cultivation, or, to use a metaphor of Maxwell's, the greatest benefits may be derived from a cross-fertilisation of the sciences. The wealth of material is an evil only from the point of view of one of whom too much may be expected. Another difficulty incident to the task, which must be faced, but cannot be overcome, is that of estimating rightly the value, and even the correctness, of recent work. It is not always that which seems at first the most important that proves in the end to be so. The history of science teems with examples of discoveries which attracted little notice at the time, but afterwards have taken root downwards and borne much fruit upwards.

One of the most striking advances of recent years is in the production and application of electricity upon a large scale—a subject to which I have already had occasion to allude in connection with the work of Sir W. Siemens. The dynamo machine is indeed founded upon discoveries of Faraday now more than half a century old; but it has required the protracted labours of many inventors to bring it to its present high degree of efficiency. Looking back at the matter, it seems strange that progress should have been so slow. I do not refer to details of design, the elaboration of which must always, I suppose, require the experience of actual work to indicate what parts are structurally weaker than they should be, or are exposed to undue wear and tear. But with regard to the main features of the problem it would almost seem as if the difficulty lay in want of faith. Long ago it was recognised that electricity derived from chemical action is (on a large scale) too expensive a source of mechanical power, notwithstanding the fact that (as proved by Joule in 1846) the conversion of electrical into mechanical work can be effected with great economy. From this it is an evident consequence that electricity may advantageously be obtained from mechanical power; and one cannot help thinking that if the fact had been borne steadily in mind, the development of the dynamo might have been much more rapid. But discoveries and inventions are apt to appear obvious when regarded from the standpoint of accomplished fact; and I draw attention to the matter only to point the moral that we do well to push the attack persistently when we can be sure beforehand that the obstacles to be overcome are only difficulties of contrivance, and that we are not vainly fighting unawares against a law of Nature.

The present development of electricity on a large scale depends, however, almost as much upon the incandescent lamp as upon the dynamo. The success of these lamps demands a very perfect vacuum—not more than about one-millionth of the normal quantity of air should remain—and it is interesting to recall that, twenty years ago, such vacua were rare even in the laboratory of the physicist. It is pretty safe to say that these wonderful results would never have been accomplished had practical applications alone been in view. The way was prepared by an army of scientific men whose main object was the advancement of knowledge, and who could scarcely have imagined that the processes which they elaborated would soon be in use on a commercial scale and intrusted to the hands of ordinary workmen.

When I speak in hopeful language of practical electricity, I do not forget the disappointment within the last year or two of many over-sanguine expectations. The enthusiasm of the inventor and promoter are necessary to progress, and it seems to be almost a law of nature that it should overpass the bounds marked out by reason and experience. What is most to be regretted is the advantage taken by speculators of the often uninstructed interest felt by the public in novel schemes by which its imagination is fired. But looking forward to the future of electric lighting, we have good ground for encouragement. Already the lighting of large passenger-ships is an assured success, and one which will be highly appreciated by those travellers who have experienced the tedium of long winter evenings unrelieved by adequate illumination. Here, no doubt, the conditions are in many respects especially favourable. As regards space, life on board ship is highly concentrated; while unity of

management and the presence on the spot of skilled engineers obviate some of the difficulties that are met with under other circumstances. At present we have no experience of a house-to-house system of illumination on a great scale and in competition with cheap gas; but preparations are already far advanced for trial on an adequate scale in London. In large institutions, such as theatres and factories, we all know that electricity is in successful and daily extending operation.

When the necessary power can be obtained from the fall of water, instead of from the combustion of coal, the conditions of the problem are far more favourable. Possibly the severity of your winters may prove an obstacle, but it is impossible to regard your splendid river without the thought arising that the day may come when the vast powers now running to waste shall be bent into your service. Such a project demands of course the most careful consideration, but it is one worthy of an intelligent and enterprising community.

The requirements of practice react in the most healthy manner upon scientific electricity. Just as in former days the science received a stimulus from the application to telegraphy, under which everything relating to measurement on a small scale acquired an importance and development for which we might otherwise have had long to wait, so now the requirements of electric lighting are giving rise to a new development of the art of measurement upon a large scale, which cannot fail to prove of scientific as well as practical importance. Mere change of scale may not at first appear a very important matter, but it is surprising how much modification it entails in the instruments, and in the processes of measurement. For instance, the resistance coils on which the electrician relies in dealing with currents whose maximum is a fraction of an ampere fail altogether when it becomes a question of hundreds, not to say thousands, of amperes.

The powerful currents, which are now at command, constitute almost a new weapon in the hands of the physicist. Effects which in old days were rare and difficult of observation may now be produced at will on the most conspicuous scale. Consider for a moment Faraday's great discovery of the "Magnetisation of Light," which Tyndall likens to the Weisshorn among mountains, as high, beautiful, and alone. This judgment (in which I fully concur) relates to the scientific aspect of the discovery, for to the eye of sense nothing could have been more insignificant. It is even possible that it might have eluded altogether the penetration of Faraday, had he not been provided with a special quality of very heavy glass. At the present day these effects may be produced upon a scale that would have delighted their discoverer, a rotation of the plane of polarisation through 180° being perfectly feasible. With the aid of modern appliances, Kundt and Röntgen in Germany, and H. Becquerel in France, have detected the rotation in gases and vapours, where, on account of its extreme smallness, it had previously escaped notice.

Again, the question of the magnetic saturation of iron has now an importance entirely beyond what it possessed at the time of Joule's early observations. Then it required special arrangements purposely contrived to bring it into prominence. Now in every dynamo machine, the iron of the field-magnets approaches a state of saturation, and the very elements of an explanation of the action require us to take the fact into account. It is indeed probable that a better knowledge of this subject might lead to improvements in the design of these machines.

Notwithstanding the important work of Rowland and Stoletow, the whole theory of the behaviour of soft iron under varying magnetic conditions is still somewhat obscure. Much may be hoped from the induction balance of Hughes, by which the marvellous powers of the telephone are applied to the discrimination of the properties of metals, as regards magnetism and electric conductivity.

The introduction of powerful alternate-current in machines by Siemens, Gordon, Ferranti, and others, is likely also to have a salutary effect in educating those so-called practical electricians whose ideas do not easily rise above ohms and volts. It has long been known that when the changes are sufficiently rapid, the phenomena are governed much more by induction, or electric inertia, than by mere resistance. On this principle much may be explained that would otherwise seem paradoxical. To take a comparatively simple case, conceive an electro-magnet wound with two contiguous wires, upon which acts a given rapidly periodic electromotive force. If one wire only be used, a certain amount of heat is developed in the circuit. Suppose now that the second wire is brought into operation in parallel—a proceeding equivalent to doubling the section of the original wire. An electrician accustomed only to constant currents would be sure to think that the heating effect would be doubled by the change, as much heat being developed in each wire separately as was at first in the single wire. But such a conclusion would be entirely erroneous. The total current, being governed practically by the self-induction of the circuit, would not be augmented by the accession of the second wire, and the total heating effect, so far from being doubled, would, in virtue of the superior conductivity, be halved.

During the last few years much interest has been felt in the reduction to an absolute standard of measurements of electromotive force, current, resistance, &c., and to this end many laborious investigations have been undertaken. The subject is one that has engaged a good deal of my own attention, and I should naturally have felt inclined to dilate upon it, but that I feel it to be too abstruse and special to be dealt with in detail upon an occasion like the present. As regards resistance, I will merely remind you that the recent determinations have shown a so greatly improved agreement that the Conference of Electricians assembled at Paris in May have felt themselves justified in defining the ohm for practical use as the resistance of a column of mercury of 0° C., one square millimetre in section, and 106 cm. in length—a definition differing by a little more than 1 per cent. from that arrived at twenty years ago by a committee of this Association.

A standard of resistance once determined upon can be embodied in a "resistance coil," and copied without much trouble, and with great accuracy. But in order to complete the electrical system, a second standard of some kind is necessary, and this is not so easily embodied in a permanent form. It might conveniently consist of a standard galvanic cell, capable of being prepared in a definite manner, whose electromotive force is once for all determined. Unfortunately, most of the batteries in ordinary use are for one reason or another unsuitable for this purpose, but the cell introduced by Mr. Latimer Clark, in which the metals are zinc in contact with saturated zinc sulphate and pure mercury in contact with mercurous sulphate, appears to give satisfactory results. According to my measurements, the electromotive force of this cell is 1·435 theoretical volts.

We may also conveniently express the second absolute electrical measurement necessary to the completion of the system by taking advantage of Faraday's law that the quantity of metal decomposed in an electrolytic cell is proportional to the whole quantity of electricity that passes. The best metal for the purpose is silver, deposited from a solution of the nitrate or of the chlorate. The results recently obtained by Prof. Kohlrausch and by myself are in very good agreement, and the conclusion that one ampere flowing for one hour decomposes 4·025 grains of silver, can hardly be in error by more than a thousandth part. This number being known, the silver voltameter gives a ready and very accurate method of measuring currents of intensity varying from one-tenth of an ampere to four or five amperes.

The beautiful and mysterious phenomena attending the discharge of electricity in nearly vacuous spaces have been investigated and in some degree explained by De La Rue, Crookes, Schuster, Moulton, and the lamented Spottiswoode, as well as by various able foreign experimenters. In a recent research Crookes has sought the origin of a bright citron-coloured band in the phosphorescent spectrum of certain earths, and after encountering difficulties and anomalies of a most bewildering kind, has succeeded in proving that it is due to yttrium, an element much more widely distributed than had been supposed. A conclusion like this is stated in a few words, but those only who have undergone similar experience are likely to appreciate the skill and perseverance of which it is the final reward.

A remarkable observation by Hall of Baltimore, from which it appeared that the flow of electricity in a conducting sheet was disturbed by magnetic force, has been the subject of much discussion. Mr. Shelford Bidwell has brought forward experiments tending to prove that the effect is of a secondary character, due in the first instance to the mechanical force operating upon the conductor of an electric current when situated in a powerful magnetic field. Mr. Bidwell's view agrees in the main with Mr. Hall's division of the metals into two groups according to the direction of the eff ct.

Without doubt the most important achievement of the older generation of scientific men has been the establishment and

application of the great laws of thermo-dynamics, or, as it is often called, the mechanical theory of heat. The first law, which asserts that heat and mechanical work can be transformed one into the other at a certain fixed rate, is now well understood by every student of physics, and the number expressing the mechanical equivalent of heat resulting from the experiments of Joule has been confirmed by the researches of others, and especially of Rowland. But the second law, which practically is even more important than the first, is only now beginning to receive the full appreciation due to it. One reason of this may be found in a not unnatural confusion of ideas. Words do not always lend themselves readily to the demands that are made upon them by a growing science, and I think that the almost unavoidable use of the word equivalent in the statement of the first law is partly responsible for the little attention that is given to the second. For the second law so far contradicts the usual statement of the first, as to assert that equivalents of heat and work are not of equal value. While work can always be converted into heat, heat can only be converted into work under certain limitations. For every practical purpose the work is worth the most, and when we speak of equivalents, we use the word in the same sort of special sense as that in which chemists speak of equivalents of gold and iron. The second law teaches us that the real value of heat, as a source of mechanical power, depends upon the temperature of the body in which it resides: the hotter the body in relation to its surroundings, the more available the heat.

In order to see the relations which obtain between the first and the second law of thermo-dynamics, it is only necessary for us to glance at the theory of the steam-engine. Not many years ago calculations were plentiful demonstrating the inefficiency of the steam-engine on the basis of a comparison of the work actually got out of the engine with the mechanical equivalent of the heat supplied to the boiler. Such calculations took into account only the first law of thermo-dynamics, which deals with the equivalents of heat and work, and have very little bearing upon the practical question of efficiency, which requires us to have regard also to the second law. According to that law the fraction of the total energy which can be converted into work depends upon the relative temperatures of the boiler and condenser; and it is, therefore, manifest that, as the temperature of the boiler cannot be raised indefinitely, it is impossible to utilise all the energy which, according to the first law of thermodynamics, is resident in the coal.

On a sounder view of the matter, the efficiency of the steam-engine is found to be so high that there is no great margin remaining for improvement. The higher initial temperature possible in the gas-engine opens out much wider possibilities, and many good judges look forward to a time when the steam-engine will have to give way to its younger rival.

To return to the theoretical question, we may say with Sir W. Thomson that, though energy cannot be destroyed, it ever tends to be dissipated, or to pass from more available to less available forms. No one who has grasped this principle can fail to recognise its immense importance in the system of the universe. Every change, chemical, thermal, or mechanical—which takes place, or can take place, in Nature, does so, at the cost of a certain amount of available energy. If, therefore, we wish to inquire whether or not a proposed transformation can take place, the question to be considered is whether its occurrence would involve dissipation of energy. If not, the transformation is (under the circumstances of the case) absolutely excluded. Some years ago, in a lecture at the Royal Institution, I endeavoured to draw the attention of chemists to the importance of the principle of dissipation in relation to their science, pointing out the error of the usual assumption that a general criterion is to be found in respect of the development of heat. For example, the solution of a salt in water is, if I may be allowed the phrase, a downhill transformation. It involves dissipation of energy, and can therefore go forward; but in many cases it is associated with the absorption rather than with the development of heat. I am glad to take advantage of the present opportunity in order to repeat my recommendation, with an emphasis justified by actual achievement. The foundations laid by Thomson now bear an edifice of no mean proportions, thanks to the labours of several physicists, among whom must be especially mentioned Willard, Gibbs, and Helmholtz. The former has elaborated a theory of the equilibrium of heterogeneous substances, wide in its principles, and we cannot doubt far-reaching in its consequences. In a series of masterly papers Helmholtz has developed the conception of *free energy* with very important applications to the theory of the galvanic cell. He points out that the mere tendency to solution bears in some cases no small proportion to the affinities more usually reckoned chemical, and contributes largely to the total electromotive force. Also in our own country Dr. Alder Wright has published some valuable experiments relating to the subject.

From the further study of electrolysis we may expect to gain improved views as to the nature of the chemical reactions, and of the forces concerned in bringing them about. I am not qualified—I wish I were—to speak to you on recent progress in general chemistry. Perhaps my feelings towards a first love may blind me, but I cannot help thinking that the next great advance, of which we have already some foreshadowing, will come on this side. And if I might without presumption venture a word of recommendation, it would be in favour of a more minute study of the simpler chemical phenomena.

Under the head of scientific mechanics it is principally in relation to fluid motion that advances may be looked for. In speaking upon this subject I must limit myself almost entirely to experimental work. Theoretical hydrodynamics, however important and interesting to the mathematician, are eminently unsuited to oral exposition. All I can do to attenuate an injustice, to which theorists are pretty well accustomed, is to refer you to the admirable reports of Mr. Hicks, published under the auspices of this Association.

The important and highly practical work of the late Mr. Froude in relation to the propulsion of ships is doubtless known to most of you. Recognising the fallacy of views then widely held as to the nature of the resistance to be overcome, he showed to demonstration that, in the case of fair-shaped bodies, we have to deal almost entirely with resistance dependent upon skin friction, and at high speeds upon the generation of surface-waves by which energy is carried off. At speeds which are moderate in relation to the size of the ship, the resistance is practically dependent upon skin friction only. Although Prof. Stokes and other mathematicians had previously published calculations pointing to the same conclusion, there can be no doubt that the view generally entertained was very different. At the first meeting of the Association which I ever attended, as an intelligent listener, at Bath in 1864, I well remember the surprise which greeted a statement by Rankine that he regarded skin friction as the only legitimate resistance to the progress of a well-designed ship. Mr. Froude's experiments have set the question at rest in a manner satisfactory to those who had little confidence in theoretical prevision.

In speaking of an explanation as satisfactory in which skin friction is accepted as the cause of resistance, I must guard myself against being supposed to mean that the nature of skin friction is itself well understood. Although its magnitude varies with the smoothness of the surface, we have no reason to think that it would disappear at any degree of smoothness consistent with an ultimate molecular structure. That it is connected with fluid viscosity is evident enough, but the *modus operandi* is still obscure.

Some important work bearing upon the subject has recently been published by Prof. O. Reynolds, who has investigated the flow of water in tubes as dependent upon the velocity of motion and upon the size of the bore. The laws of motion in capillary tubes, discovered experimentally by Poiseuille, are in complete harmony with theory. The resistance varies as the velocity, and depends in a direct manner upon the constant of viscosity. But when we come to the larger pipes and higher velocities with which engineers usually have to deal, the theory which presupposes a regularly stratified motion evidently ceases to be applicable, and the problem becomes essentially identical with that of skin friction in relation to ship propulsion. Prof. Reynolds has traced with much success the passage from the one state of things to the other, and has proved the applicability under these complicated conditions of the general laws of dynamical similarity as adapted to viscous fluids by Prof. Stokes. In spite of the difficulties which beset both the theoretical and experimental treatment, we may hope to attain before long to a better understanding of a subject which is certainly second to none in scientific as well as practical interest.

As also closely connected with the mechanics of viscous fluids, I must not forget to mention an important series of experiments upon the friction of oiled surfaces, recently executed by Mr. Tower for the Institution of Mechanical Engineers. The results

go far towards upsetting some ideas hitherto widely admitted. When the lubrication is adequate, the friction is found to be nearly independent of the load, and much smaller than is usually supposed, giving a coefficient as low as 1/1000. When the layer of oil is well formed, the pressure between the solid surfaces is really borne by the fluid, and the work lost is spent in shearing, that is, in causing one stratum of the oil to glide over another.

In order to maintain its position, the fluid must possess a certain degree of viscosity, proportionate to the pressure; and even when this condition is satisfied, it would appear to be necessary that the layer should be thicker on the ingoing than on the outgoing side. We may, I believe, expect from Prof. Stokes a further elucidation of the processes involved. In the meantime, it is obvious that the results already obtained are of the utmost value, and fully justify the action of the Institution in devoting a part of its resources to experimental work. We may hope indeed that the example thus wisely set may be followed by other public bodies associated with various departments of industry.

I can do little more than refer to the interesting observations of Prof. Darwin, Mr. Hunt, and M. Forel on ripplemark. The processes concerned would seem to be of a rather intricate character, and largely dependent upon fluid viscosity. It may be noted indeed that most of the still obscure phenomena of hydrodynamics require for their elucidation a better comprehension of the laws of viscous motion. The subject is one which offers peculiar difficulties. In some problems in which I have lately been interested, a circulating motion presents itself of the kind which the mathematician excludes from the first when he is treating of fluids destitute altogether of viscosity. The intensity of this motion proves, however, to be independent of the coefficient of viscosity, so that it cannot be correctly dismissed from consideration as a consequence of a supposition that the viscosity is infinitely small. The apparent breach of continuity can be explained, but it shows how much care is needful in dealing with the subject, and how easy it is to fall into error.

The nature of gaseous viscosity, as due to the diffusion of momentum, has been made clear by the theoretical and experimental researches of Maxwell. A flat disk moving in its own plane between two parallel solid surfaces is impeded by the necessity of shearing the intervening layers of gas, and the magnitude of the hindrance is proportional to the velocity of the motion and to the viscosity of the gas, so that under similar circumstances this effect may be taken as a measure, or rather definition, of the viscosity. From the dynamical theory of gases, to the development of which he contributed so much, Maxwell drew the startling conclusion that the viscosity of a gas should be independent of its density,—that within wide limits the resistance to the moving disk should be scarcely diminished by pumping out the gas, so as to form a partial vacuum. Experiment fully confirmed this theoretical anticipation—one of the most remarkable to be found in the whole history of science, and proved that the swinging disk was retarded by the gas, as much when the barometer stood at half an inch as when it stood at thirty inches. It was obvious, of course, that the law must have a limit, that at a certain point of exhaustion the gas must begin to lose its power; and I remember discussing with Maxwell, soon after the publication of his experiments, the whereabouts of the point at which the gas would cease to produce its ordinary effect. His apparatus, however, was quite unsuited for high degrees of exhaustion, and the failure of the law was first observed by Kundt and Warburg, at pressures below 1 mm. of mercury. Subsequently the matter has been thoroughly examined by Crookes, who extended his observations to the highest degrees of exhaustion as measured by MacLeod's gauge. Perhaps the most remarkable results relate to hydrogen. From the atmospheric pressure of 760 mm. down to about ½ mm. of mercury the viscosity is sensibly constant. From this point to the highest vacua, in which less than one-millionth of the original gas remains, the coefficient of viscosity drops down gradually to a small fraction of its original value. In these vacua Mr. Crookes regards the gas as having assumed a different, ultra-gaseous condition; but we must remember that the phenomena have relation to the other circumstances of the case, especially the dimensions of the vessel, as well as to the condition of the gas.

Such an achievement as the prediction of Maxwell's law of viscosity has of course drawn increased attention to the dynamical theory of gases. The success which has attended the theory in the hands of Clausius, Maxwell, Boltzmann, and other mathematicians, not only in relation to viscosity, but over a large part of the entire field of our knowledge of gases, proves that some of its fundamental postulates are in harmony with the reality of Nature. At the same time it presents serious difficulties; and we cannot but feel that, while the electrical and optical properties of gases remain out of relation to the theory, no final judgment is possible. The growth of experimental knowledge may be trusted to clear up many doubtful points, and a younger generation of theorists will bring to bear improved mathematical weapons. In the meantime we may fairly congratulate ourselves on the possession of a guide which has already conducted us to a position which could hardly otherwise have been attained.

In optics attention has naturally centred upon the spectrum. The mystery attaching to the invisible rays lying beyond the red has been fathomed to an extent that, a few years ago, would have seemed almost impossible. By the use of special photographic methods Abney has mapped out the peculiarities of this region with such success that our knowledge of it begins to be comparable with that of the parts visible to the eye. Equally important work has been done by Langley, using a refined invention of his own based upon the principle of Siemens' pyrometer. This instrument measures the actual energy of the radiation, and thus expresses the effects of various parts of the spectrum upon a common scale, independent of the properties of the eye and of sensitive photographic preparations. Interesting results have also been obtained by Becquerel, whose method is founded upon a curious action of the ultra-red rays in enfeebling the light emitted by phosphorescent substances. One of the most startling of Langley's conclusions relates to the influence of the atmosphere in modifying the quality of solar light. By the comparison of observations made through varying thicknesses of air he shows that the atmospheric absorption tells most upon the light of high refrangibility; so that to an eye situated outside the atmosphere the sun would present a decidedly bluish tint. It would be interesting to compare the experimental numbers with the law of scattering of light by small particles given some years ago as the result of theory. The demonstration by Langley of the inadequacy of Cauchy's law of dispersion to represent the relation between refrangibility and wave-length in the lower part of the spectrum must have an important bearing upon optical theory.

The investigation of the relation of the visible and ultra-violet spectrum to various forms of matter has occupied the attention of a host of able workers, among whom none have been more successful than my colleagues at Cambridge, Profs. Liveing and Dewar. The subject is too large both for the occasion and for the individual, and I must pass it by. But, as more closely related to optics proper, I cannot resist recalling to your notice a beautiful application of the idea of Doppler to the discrimination of the origin of certain lines observed in the solar spectrum. If a vibrating body have a general motion of approach or recession, the waves emitted from it reach the observer with a frequency which in the first case exceeds, and in the second case falls short of, the real frequency of the vibrations themselves. The consequence is that, if a glowing gas be in motion in the line of sight, the spectral lines are thereby displaced from the position that they would occupy were the gas at rest—a principle which, in the hands of Huggins and others, has led to a determination of the motion of certain fixed stars relatively to the solar system. But the sun is itself in rotation, and thus the position of a solar spectral line is slightly different according as the light comes from the advancing or from the retreating limb. This displacement was, I believe, first observed by Thollon; but what I desire now to draw attention to is the application of it by Cornu to determine whether a line is of solar or atmospheric origin. For this purpose a small image of the sun is thrown upon the slit of the spectroscope, and caused to vibrate two or three times a second, in such a manner that the light entering the instrument comes alternately from the advancing and retreating limbs. Under these circumstances a line due to absorption within the sun appears to tremble, as the result of slight alternately opposite displacements. But if the seat of the absorption be in the atmosphere it is a matter of indifference from what part of the sun the light originally proceeds, and the line maintains its position in spite of the oscillation of the image upon the slit of the spectroscope. In this way Cornu was able to make a discrimination which can only otherwise be effected by a difficult comparison of appearances under various solar altitudes.

The instrumental weapon of investigation, the spectroscope itself, has made important advances. On the theoretical side, we have for our guidance the law that the optical power in gratings is proportional to the total number of lines accurately ruled, without regard to the degree of closeness, and in prisms that it is proportional to the thickness of glass traversed. The magnificent gratings of Rowland are a new power in the hands of the spectroscopist, and as triumphs of mechanical art seem to be little short of perfection. In our own report for 1882 Mr. Mallock has described a machine, constructed by him, for ruling large diffraction gratings, similar in some respects to that of Rowland.

The great optical constant, the velocity of light, has been the subject of three distinct investigations by Cornu, Michelson, and Forbes. As may be supposed, the matter is of no ordinary difficulty, and it is therefore not surprising that the agreement should be less decided than could be wished. From their observations, which were made by a modification of Fizeau's method of the toothed wheel, Young and Forbes drew the conclusion that the velocity of light *in vacuo* varies from colour to colour, to such an extent that the velocity of blue light is nearly 2 per cent. greater than that of red light. Such a variation is quite opposed to existing theoretical notions, and could only be accepted on the strongest evidence. Mr. Michelson, whose method (that of Foucault) is well suited to bring into prominence a variation of velocity with wave-length, informs me that he has recently repeated his experiments with special reference to the point in question, and has arrived at the conclusion that no variation exists comparable with that asserted by Young and Forbes. The actual velocity differs little from that found from his first series of experiments, and may be taken to be 299,800 km. per second.

It is remarkable how many of the playthings of our childhood give rise to questions of the deepest scientific interest. The top is, or may be, understood, but a complete comprehension of the kite and of the soap-bubble would carry us far beyond our present stage of knowledge. In spite of the admirable investigations of Plateau, it still remains a mystery why soapy water stands almost alone among fluids as a material for bubbles. The beautiful development of colour was long ago ascribed to the interference of light, called into play by the gradual thinning of the film. In accordance with this view the tint is determined solely by the thickness of the film, and the refractive index of the fluid. Some of the phenomena are, however, so curious as to have led excellent observers like Brewster to reject the theory of thin plates, and to assume the secretion of various kinds of colouring matter. If the rim of a wine-glass be dipped in soapy water, and then held in a vertical position, horizontal bands soon begin to show at the top of the film, and extend themselves gradually downwards. According to Brewster these bands are not formed by the "subsidence and gradual thinning of the film," because they maintain their horizontal position when the glass is turned round its axis. The experiment is both easy and interesting; but the conclusion drawn from it cannot be accepted. The fact is that the various parts of the film cannot quickly alter their thickness, and hence when the glass is rotated they rearrange themselves in order of superficial density, the thinner parts floating up over, or through, the thicker parts. Only thus can the tendency be satisfied for the centre of gravity to assume the lowest possible position.

When the thickness of a film falls below a small fraction of the length of a wave of light, the colour disappears and is replaced by an intense blackness. Profs. Reinold and Rücker have recently made the remarkable observation that the whole of the black region, soon after its formation, is of uniform thickness, the passage from the black to the coloured portions being exceedingly abrupt. By two independent methods they have determined the thickness of the black film to lie between seven and fourteen millionths of a millimetre; so that the thinnest films correspond to about one-seventieth of a wave-length of light. The importance of these results in regard to molecular theory is too obvious to be insisted upon.

The beautiful inventions of the telephone and the phonograph, although in the main dependent upon principles long since established, have imparted a new interest to the study of acoustics. The former, apart from its uses in every-day life, has become in the hands of its inventor, Graham Bell, and of Hughes, an instrument of first-class scientific importance. The theory of its action is still in some respects obscure, as is shown by the comparative failure of the many attempts to improve it. In connection with some explanations that have been offered, we do well to remember that molecular changes in solid masses are inaudible in themselves, and can only be manifested to our ears by the generation of a to-and-fro motion of the external surface extending over a sensible area. If the surface of a solid remains undisturbed, our ears can tell us nothing of what goes on in the interior.

In theoretical acoustics progress has been steadily maintained, and many phenomena which were obscure twenty or thirty years ago, have since received adequate explanation. If some important practical questions remain unsolved, one reason is that they have not yet been definitely stated. Almost everything in connection with the ordinary use of our senses presents peculiar difficulties to scientific investigation. Some kinds of information with regard to their surroundings are of such paramount importance to successive generations of living beings, that they have learned to interpret indications which, from a physical point of view, are of the slenderest character. Every day we are in the habit of recognising, without much difficulty, the quarter from which a sound proceeds, but by what steps we attain that end has not yet been satisfactorily explained. It has been proved that when proper precautions are taken we are unable to distinguish whether a pure tone (as from a vibrating tuning-fork held over a suitable resonator) comes to us from in front or from behind. This is what might have been expected from an *a priori* point of view; but what would not have been expected is that with almost any other sort of sound, from a clap of the hands to the clearest vowel sound, the discrimination is not only possible, but easy and instinctive. In these cases it does not appear how the possession of two ears helps us, though there is some evidence that it does; and even when sounds come to us from the right or left, the explanation of the ready discrimination which is then possible with pure tones is not so easy as might at first appear. We should be inclined to think that the sound was heard much more loudly with the ear that is turned towards than with the ear that is turned from it, and that in this way the direction was recognised. But if we try the experiment we find that, at any rate with notes near the middle of the musical scale, the difference of loudness is by no means so very great. The wave lengths of such notes are long enough in relation to the dimensions of the head to forbid the formation of anything like a sound shadow in which the averted ear might be sheltered.

In concluding this imperfect survey of recent progress in physics, I must warn you emphatically that much of great importance has been passed over altogether. I should have liked to speak to you of those far-reaching speculations, especially associated with the name of Maxwell, in which light is regarded as a disturbance in an electro-magnetic medium. Indeed, at one time I had thought of taking the scientific work of Maxwell as the principal theme of this address. But, like most men of genius, Maxwell delighted in questions too obscure and difficult for hasty treatment, and thus much of his work could hardly be considered upon such an occasion as the present. His biography has recently been published, and should be read by all who are interested in science and in scientific men. His many-sided character, the quaintness of his humour, the penetration of his intellect, his simple but deep religious feeling, the affection between son and father, the devotion of husband to wife, all combine to form a rare and fascinating picture. To estimate rightly his influence upon the present state of science, we must regard not only the work that he executed himself, important as that was, but also the ideas and the spirit which he communicated to others. Speaking for myself as one who in a special sense entered into his labours, I should find it difficult to express adequately my feeling of obligation. The impress of his thoughts may be recognised in much of the best work of the present time. As a teacher and examiner he was well acquainted with the almost universal tendency of uninstructed minds to elevate phrases above things: to refer, for example, to the principle of the conservation of energy for an explanation of the persistent rotation of a fly-wheel, almost in the style of the doctor in "Le Malade Imaginaire," who explains the fact that opium sends you to sleep by its soporific virtue. Maxwell's endeavour was always to keep the facts in the foreground, and to his influence, in conjunction with that of Thomson and Helmholtz, is largely due that elimination of unnecessary hypothesis which is one of the distinguishing characteristics of the science of the present day.

In speaking unfavourably of superfluous hypothesis let me not be misunderstood. Science is nothing without generalisations. Detached and ill-assorted facts are only raw material, and in the absence of a theoretical solvent have but little nutritive value. At the present time and in some departments the accumulation of material is so rapid that there is danger of indigestion. By a fiction as remarkable as any to be found in law, what has once been published, even though it be in the Russian language, is usually spoken of as "known," and it is often forgotten that the rediscovery in the library may be a more difficult and uncertain process than the first discovery in the laboratory. In this matter we are greatly dependent upon annual reports and abstracts, issued principally in Germany, without which the search for the discoveries of a little-known author would be well-nigh hopeless. Much useful work has been done in this direction in connection with our Association. Such critical reports as those upon hydrodynamics, upon tides, and upon spectroscopy, guide the investigator to the points most requiring attention, and in discussing past achievements contribute in no small degree to future progress. But, though good work has been done, much yet remains to do.

If, as is sometimes supposed, science consisted in nothing but the laborious accumulation of facts, it would soon come to a standstill, crushed, as it were, under its own weight. The suggestion of a new idea, or the detection of a law, supersedes much that had previously been a burden upon the memory, and by introducing order and coherence facilitates the retention of the remainder in an available form. Those who are acquainted with the writings of the older electricians will understand my meaning when I instance the discovery of Ohm's law as a step by which the science was rendered easier to understand and to remember. Two processes are thus at work side by side, the reception of new material and the digestion and assimilation of the old; and as both are essential, we may spare ourselves the discussion of their relative importance. One remark, however, should be made. The work which deserves, but I am afraid does not always receive, the most credit, is that in which discovery and explanation go hand in hand, in which not only are new facts presented, but their relation to old ones is pointed out.

In making one's self acquainted with what has been done in any subject, it is good policy to consult first the writers of highest general reputation. Although in scientific matters we should aim at independent judgment, and not rely too much upon authority, it remains true that a good deal must often be taken upon trust. Occasionally an observation is so simple and easily repeated, that it scarcely matters from whom it proceeds; but as a rule it can hardly carry full weight when put forward by a novice whose care and judgment there has been no opportunity of testing, and whose irresponsibility may tempt him to "take shots," as it is called. Those who have had experience in accurate work know how easy it would be to save time and trouble by omitting precautions and passing over discrepancies, and yet, even without dishonest intention, to convey the impression of conscientious attention to details. Although the most careful and experienced cannot hope to escape occasional mistakes, the effective value of this kind of work depends much upon the reputation of the individual responsible for it.

In estimating the present position and prospects of experimental science, there is good ground for encouragement. The multiplication of laboratories gives to the younger generation opportunities such as have never existed before, and which excite the envy of those who have had to learn in middle life much that now forms part of an undergraduate course. As to the management of such institutions, there is room for a healthy difference of opinion. For many kinds of original work, especially in connection with accurate measurement, there is need of expensive apparatus; and it is often difficult to persuade a student to do his best with imperfect appliances when he knows that by other means a better result could be attained with greater facility. Nevertheless it seems to me important to discourage too great reliance upon the instrument-maker. Much of the best original work has been done with the homeliest appliances; and the endeavour to turn to the best account the means that may be at hand develops ingenuity and resource more than the most elaborate determinations with ready-made instruments. There is danger otherwise that the experimental education of a plodding student should be too mechanical and artificial, so that he is puzzled by small changes of apparatus much as many school-boys are puzzled by a transposition of the letters in a diagram of Euclid.

From the general spread of a more scientific education we are warranted in expecting important results. Just as there are some brilliant literary men with an inability, or at least a distaste practically amounting to inability, for scientific ideas, so there are a few with scientific tastes whose imaginations are never touched by merely literary studies. To save these from intellectual stagnation during several important years of their lives is something gained; but the thoroughgoing advocates of scientific education aim at much more. To them it appears strange, and almost monstrous, that the dead languages should hold the place they do in general education; and it can hardly be denied that their supremacy is the result of routine rather than of argument. I do not myself take up the extreme position. I doubt whether an exclusively scientific training would be satisfactory; and where there is plenty of time and a literary aptitude I can believe that Latin and Greek may make a good foundation. But it is useless to discuss the question upon the supposition that the majority of boys attain either to a knowledge of the languages or to an appreciation of the writings of the ancient authors. The contrary is notoriously the truth; and the defenders of the existing system usually take their stand upon the excellence of its discipline. From this point of view there is something to be said. The laziest boy must exert himself a little in puzzling out a sentence with grammar and dictionary, while instruction and supervision are easy to organise and not too costly. But when the case is stated plainly, few will agree that we can afford so entirely to disregard results. In after life the intellectual energies are usually engrossed with business, and no further opportunity is found for attacking the difficulties which block the gateways of knowledge. Mathematics, especially, if not learned young, are likely to remain unlearned. I will not further insist upon the educational importance of mathematics and science, because with respect to them I shall probably be supposed to be prejudiced. But of modern languages I am ignorant enough to give value to my advocacy. I believe that French and German, if properly taught, which I admit they rarely are at present, would go far to replace Latin and Greek from a disciplinary point of view, while the actual value of the acquisition would, in the majority of cases, be incomparably greater. In half the time usually devoted without success to the classical languages, most boys could acquire a really serviceable knowledge of French and German. History and the serious study of English literature, now shamefully neglected, would also find a place in such a scheme.

There is one objection often felt to a modernised education, as to which a word may not be without use. Many excellent people are afraid of science as tending towards materialism. That such apprehension should exist is not surprising, for unfortunately there are writers, speaking in the name of science, who have set themselves to foster it. It is true that among scientific men, as in other classes, crude views are to be met with as to the deeper things of Nature; but that the life-long beliefs of Newton, of Faraday, and of Maxwell are inconsistent with the scientific habit of mind is surely a proposition which I need not pause to refute. It would be easy, however, to lay too much stress upon the opinions of even such distinguished workers as these. Men who devote their lives to investigation cultivate a love of truth for its own sake, and endeavour instinctively to clear up, and not, as is too often the object in business and politics, to obscure, a difficult question. So far the opinion of a scientific worker may have a special value; but I do not think that he has a claim, superior to that of other educated men, to assume the attitude of a prophet. In his heart he knows that underneath the theories that he constructs there lie contradictions which he cannot reconcile. The higher mysteries of being, if penetrable at all by human intellect, require other weapons than those of calculation and experiment.

Without encroaching upon grounds appertaining to the theologian and the philosopher, the domain of natural science is surely broad enough to satisfy the wildest ambition of its devotees. In other departments of human life and interest, true progress is rather an article of faith than a rational belief; but in science a retrograde movement is, from the nature of the case, almost impossible. Increasing knowledge brings with it increasing power, and great as are the triumphs of the present century, we may well believe that they are but a foretaste of what discovery and invention have yet in store for mankind. Encouraged by the thought that our labours cannot be thrown away, let us redouble our efforts in the noble struggle. In the

Old World and in the New, recruits must be enlisted to fill the place of those whose work is done. Happy should I be if, through this visit of the Association, or by any words of mine, a larger measure of the youthful activity of the West could be drawn into this service. The work may be hard, and the discipline severe, but the interest never fails, and great is the privilege of achievement.

SECTION A

MATHEMATICAL AND PHYSICAL SCIENCE

OPENING ADDRESS BY PROF. SIR WILLIAM THOMSON, M.A., LL.D., D.C.L., F.R.SS.L. & E., F.R.A.S., PRESIDENT OF THE SECTION

Steps towards a Kinetic Theory of Matter

THE now well-known kinetic theory of gases is a step so important in the way of explaining seemingly static properties of matter by motion, that it is scarcely possible to help anticipating in idea the arrival at a complete theory of matter, in which all its properties will be seen to be merely attributes of motion. If we are to look for the origin of this idea, we must go back to Democritus, Epicurus, and Lucretius. We may then, I believe, without missing a single step, skip 1800 years. Early last century we find in Malebranche's "Recherche de la Verité," the statement that "La dureté de corps" depends on "petits tourbillons."[1] These words, embedded in a hopeless mass of unintelligible statements of the physical, metaphysical, and theological philosophies of the day, and unsupported by any explanation, elucidation, or illustration throughout the rest of the three volumes, and only marred by any other single sentence or word to be found in the great book, still do express a distinct conception, which forms a most remarkable step towards the kinetic theory of matter. A little later we have Daniel Bernoulli's promulgation of what we now accept as a surest article of scientific faith—the kinetic theory of gases. He, so far as I know, thought only of the Boyle's and Marriot's law of the "spring of air," as Boyle called it, without reference to change of temperature or the augmentation of its pressure if not allowed to expand for elevation of temperature, a phenomenon which perhaps he scarcely knew, still less the elevation of temperature produced by compression, and the lowering of temperature by dilatation, and the consequent necessity of waiting for a fraction of a second or a few seconds of time (with apparatus of ordinary experimental magnitude), to see a subsidence from a larger change of pressure, down to the amount of change that verifies Boyle's law. The consideration of these phenomena forty years ago by Joule, in connection with Bernoulli's original conception, formed the foundation of the kinetic theory of gases as we now have it. But what a splendid and useful building has been placed on this foundation by Clausius and Maxwell, and what a beautiful ornament we see on the top of it in the radiometer of Crookes, securely attached to it by the happy discovery of Tait and Dewar,[2] that the length of the free path of the residual molecules of air in a good modern vacuum may amount to several inches. Clausius' and Maxwell's explanations of the diffusion of gases, and of thermal conduction in gases, their charmingly intelligible conclusion that in gases the diffusion of heat is just a little more rapid than the diffusion of molecules, because of the interchange of energy in collisions between molecules,[3] while the chief transference of heat is by actual transport of the molecules themselves, and Maxwell's explanation of the viscosity of gases, with the absolute numerical relations which the work of those two great discoverers found among the three properties of diffusion, thermal conduction, and viscosity, have annexed to the domain of science a vast and ever-growing province.

Rich as it is in practical results, the kinetic theory of gases, as hitherto developed, stops absolutely short at the atom or molecule, and gives not even a suggestion towards explaining the properties in virtue of which the atoms or molecules mutually influence one another. For some guidance towards a deeper and more comprehensive theory of matter, we may look back with advantage to the end of last century, and the beginning of this century, and find Rumford's conclusion regarding the heat generated in boring a brass gun: "It appears to me to be extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated in the manner the heat was excited and communicated in these experiments, except it be MOTION," and Davy's still more suggestive statements: "The phenomena of repulsion are not dependent on a peculiar elastic fluid for their existence. . . ." "Heat may be defined as a peculiar motion, probably a vibration, of the corpuscles of bodies, tending to separate them. . . ." "To distinguish this motion from others, and to signify the causes of our sensations of heat, &c., the name *repulsive* motion has been adopted." Here we have a most important idea. It would be somewhat a bold figure of speech to say the earth and moon are kept apart by a repulsive motion; and yet, after all, what is centrifugal force but a repulsive motion, and may it not be that there is no such thing as repulsion, and that it is solely by inertia that what seems to be repulsion is produced? Two bodies fly together, and, accelerated by mutual attraction, if they do not precisely hit one another, they cannot but separate in virtue of the inertia of their masses. So, after dashing past one another in sharply concave curves round their common centre of gravity, they fly asunder again. A careless onlooker might imagine they had repelled one another, and might not notice the difference between what he actually sees and what he would see if the two bodies had been projected with great velocity towards one another, and either colliding and rebounding, or repelling one another into sharply convex continuous curves, fly asunder again.

Joule, Clausius, and Maxwell, and no doubt Daniel Bernoulli himself, and I believe every one who has hitherto written or done anything very explicit in the kinetic theory of gases, has taken the mutual action of molecules in collision as repulsive. May it not after all be attractive? This idea has never left my mind since I first read Davy's "Repulsive Motion," about thirty-five years ago, but I never made anything of it, at all events have not done so until to-day (June 16, 1884)—if this can be said to be making anything of it—when, in endeavouring to prepare the present address, I notice that Joule's and my own old experiments[1] on the thermal effect of gases expanding from a high-pressure vessel through a porous plug, proves the less dense gas to have greater intrinsic *potential* energy than the denser gas, if we assume the ordinary hypothesis regarding the temperature of a gas, according to which two gases are of equal temperatures[2] when the kinetic energies of their constituent molecules are of equal average amounts per molecule.

Think of the thing thus. Imagine a great multitude of particles inclosed by a boundary which may be pushed inwards in any part all round at pleasure. Now station an engineer corps of Maxwell's army of sorting demons all round the inclosure, with orders to push in the boundary diligently everywhere, when none of the besieged troops are near, and to do nothing when any of them are seen approaching, and until after they have turned again inwards. The result will be that, with exactly the same sum of kinetic and potential energies of the same inclosed multitude of particles, the throng has been caused to be denser. Now Joule's and my own old experiments on the efflux of air prove that if the crowd be common air, or

[1] "Preuve de la supposition que j'ay faite : Que la matière subtile ou éthérée est nécessairement composée de PETITS TOURBILLONS ; et qu'ils sont les causes naturelles de tous les changements qui arrivent à la matière ; ce que je confirme par l'explication des effets le plus généraux de la Physique, tels que sont la dureté des corps, leur fluidité, leur pesanteur, leur légèreté, la lumière et la réfraction et réflexion de ses rayons."—Malebranche, "Recherche de la Vérité," 1712.

[2] *Proc.* R. S. E., March 2, 1874, and July 5, 1875.

[3] On the other hand, in liquids, on account of the crowdedness of the molecules, the diffusion of heat must be chiefly by interchange of energies between the molecules, and should be, as experiment proves it is, enormously more rapid than the diffusion of the molecules themselves, and this again ought to be much less rapid than either the material or thermal diffusivities of gases. Thus the diffusivity of common salt through water was found by Fick to be as small as ·0000112 square centimetres per second; nearly 200 times as great as this is the diffusivity of heat through water, which was found by J. T. Bottomley to be about ·002 square centimetres per second. The material diffusivities of gases, according to Loschmidt's experiments, range from ·098 (the interdiffusivity of carbonic acid and nitrous oxide) to ·642 (the interdiffusivity of carbonic oxide and hydrogen), while the thermal diffusivities of gases, calculated according to Clausius' and Maxwell's kinetic theory of gases, are ·089 for carbonic acid, ·16 for common air or other gases of nearly the same density, and 1·12 for hydrogen (all, both material and thermal, being reckoned in square centimetres per second).

[1] Republished in Sir W. Thomson's "Mathematical and Physical Papers," vol. i. Article xlix. p. 381.

[2] That this is a mere hypothesis has been scarcely remarked by the founders themselves, nor by almost any writer on the kinetic theory of gases. No one has yet examined the question: What is the condition as [illegible] average distribution of kinetic energy, which is ultimately fulfilled by [illegible] septum which [illegible] interchange of kinetic energy by collisions against itself? Indeed I do not know but that the present is the very first statement which has ever been published of this condition of the problem of equal temperatures between two gaseous masses.

oxygen, or nitrogen, or carbonic acid, the temperature is a little higher in the denser than in the rarer condition when the energies are the same. By the hypothesis, equality of temperature between two different gases or two portions of the same gas at different densities means equality of kinetic energies in the same number of molecules of the two. From our observations proving the temperature to be higher, it therefore follows that the potential energy is smaller in the condensed crowd. This—always, however, under protest as to the temperature hypothesis—proves some degree of attraction among the molecules, but it does not prove ultimate attraction between two molecules in collision, or at distances much less than the average mutual distance of nearest neighbours in the multitude. The collisional force might be repulsive, as generally supposed hitherto, and yet attraction might predominate in the whole reckoning of difference between the intrinsic potential energies of the more dense and less dense multitudes. It is, however, remarkable that the explanation of the propagation of sound through gases, and even of the positive fluid pressure of a gas against the sides of the containing vessel, according to the kinetic theory of gases, is quite independent of the question whether the ultimate collisional force is attractive or repulsive. Of course it must be understood that, if it is attractive, the particles must be so small that they hardly ever meet—they would have to be infinitely small to *never* meet—that, in fact, they meet so seldom, in comparison with the number of times their courses are turned through large angles by attraction, that the influence of these purely attractive collisions is preponderant over that of the comparatively very rare impacts from actual contact. Thus, after all, the train of speculation suggested by Davy's "Repul ive Motion" does not allow us to escape from the idea of true repulsion, does not do more than let us say it is of no consequence, nor even say this with truth, because, if there are impacts at all, the nature of the force during the impact and the effects of the mutual impacts, however rare, cannot be evaded in any attempt to realise a conception of the kinetic theory of gases. And in fact, unless we are satisfied to imagine the atoms of a gas as mathematical points endowed with inertia, and, as according to Boscovich, endowed with forces of mutual positive and negative attraction, varying according to some definite function of the distance, we cannot avoid the question of impacts, and of vibrations and rotations of the molecules resulting from impacts, and we must look distinctly on each molecule as being either a little elastic solid or a configuration of motion in a continuous all-pervading liquid. I do not myself see how we can ever permanently rest anywhere short of this last view; but it would be a very pleasant temporary resting-place on the way to it if we could, as it were, make a mechanical model of a gas out of little pieces of round perfectly elastic solid matter, flying about through the space occupied by the gas, and colliding with one another and against the sides of the containing vessel. This is, in fact, all we have of the kinetic theory of gases up to the present time, and this has done for us, in the hands of Clausius and Maxwell, the great things which constitute our first step towards a molecular theory of matter. Of course from it we should have to go on to find an explanation of the elasticity and all the other properties of the molecules themselves, a subject vastly more complex and difficult than the gaseous properties, for the explanation of which we assume the elastic molecule; but without any explanation of the properties of the molecule itself, with merely the assumption that the molecule has the requisite properties, we might rest happy for a while in the contemplation of the kinetic theory of gases, and its explanation of the gaseous properties, which is not only stupendously important as a step towards a more thoroughgoing theory of matter, but is undoubtedly the expression of a perfectly intelligible and definite set of facts in Nature. But alas for our mechanical model consisting of the cloud of little elastic solids flying about amongst one another. Though each particle have absolutely perfect elasticity, the end must be pretty much the same as if it were but imperfectly elastic. The average effect of repeated and repeated mutual collisions must be to gradually convert all the translational energy into energy of shriller and shriller vibrations of the molecule. It seems certain that each collision must have something more of energy in vibrations of very finely divided nodal parts than there was of energy in such vibrations before the impact. The more minute this nodal subdivision, the less must be the tendency to give up part of the vibrational energy into the shape of translational energy in the course of a collision, and I think it is rigorously demonstrable that the whole translational energy must ultimately become transformed into vibrational energy of higher and higher nodal subdivisions if each molecule is a continuous elastic solid. Let us, then, leave the kinetic theory of gases for a time with this difficulty unsolved, in the hope that we or others after us may return to it, armed with more knowledge of the properties of matter, and with sharper mathematical weapons to cut through the barrier which at present hides from us any view of the molecule itself, and of the effects other than mere change of translational motion which it experiences in collision.

To explain the elasticity of a gas was the primary object of the kinetic theory of gases. This object is only attainable by the assumption of an elasticity more complex in character, and more difficult of explanation, than the elasticity of gases—the elasticity of a solid. Thus, even if the fatal fault in the theory, to which I have alluded, did not exist, and if we could be perfectly satisfied with the kinetic theory of gases founded on the collisions of elastic solid molecules, there would still be beyond it a grander theory which need not be considered a chimerical object of scientific ambition—to explain the elasticity of solids. But we may be stopped when we commence to look in the direction of such a theory with the cynical question: What do you mean by explaining a property of matter? As to being stopped by any such question, all I can say is that if engineering were to be all and to end all physical science, we should perforce be content with merely finding properties of matter by observation, and using them for practical purposes. But I am sure very few, if any, engineers are practically satisfied with so narrow a view of their noble profession. They must and do patiently observe, and discover by observation, properties of matter, and results of material combinations. But deeper questions are always present, and always fraught with interest to the true engineer, and he will be the last to give weight to any other objection to any attempt to see below the surface of things than the practical question: Is it likely to prove wholly futile? But now, instead of imagining the question: What do you mean by explaining a property of matter? to be put cynically, and letting ourselves be irritated by it, suppose we give to the questioner credit for being sympathetic, and condescend to try and answer his question. We find it not very easy to do so. All the properties of matter are so connected that we can scarcely imagine one *thoroughly explained* without our seeing its relation to all the others, without in fact having the explanation of all, and till we have this we cannot tell what we mean by "explaining a property," or "explaining the properties" of matter. But though this consummation may never be reached by man, the progress of science may be, I believe will be, step by step towards it, on many different roads converging towards it from all sides. The kinetic theory of gases is, as I have said, a true step on one of the roads. On the very distinct road of chemical science, St. Clair Deville arrived at his grand theory of dissociation without the slightest aid from the kinetic theory of gases. The fact that he worked it out solely from chemical observation and experiment, and expounded it to the world without any hypothesis whatever, and seemingly even without consciousness of the beautiful explanation it has in the kinetic theory of gases, secured for it immediately an independent solidity and importance as a chemical theory when he first promulgated it, to which it might even by this time scarcely have attained if it had first been suggested as a probability indicated by the kinetic theory of gases, and been only afterwards confirmed by observation. Now, however, guided by the views which Clausius and Williamson have given us of the continuous interchange of partners between the compound molecules constituting chemical compounds in the gaseous state, we see in Deville's theory of dissociation a point of contact of the most transcendent interest between the chemical and physical lines of scientific progress.

To return to elasticity: if we could make out of matter devoid of elasticity a combined system of relatively moving parts which, in virtue of motion, has the essential characteristics of an elastic body, this would surely be, if not positively a step in the kinetic theory of matter, at least a finger-post pointing a way which we may hope will lead to a kinetic theory of matter. Now this, as I have already shown,[1] we can do in several ways. In the case of the last of the communications referred to, of which only the title has hitherto been published, I showed that, from the

[1] Paper on "Vortex Atoms," *Proc.* R. S. E. February 1867; abstract of a lecture before the Royal Institution of Great Britain, March 4, 1881, on "Elasticity Viewed as possibly a Mode of Motion"; Thomson and Tait's "Natural Philosophy," second edition, part 1, §§ 345 viii. to 345 xxvii.; "On Oscillation and Waves in an Adynamic Gyrostatic System" (title only), *Proc.* R. S. E. March 1883.

mathematical investigation of a gyrostatically dominated combination contained in the passage of Thomson and Tait's "Natural Philosophy" referred to, it follows that any ideal system of material particles, acting on one another mutually through massless connecting springs, may be perfectly imitated in a model consisting of rigid links jointed together, and having rapidly rotating fly-wheels pivoted on some or on all of the links. The imitation is not confined to cases of equilibrium. It holds also for vibration produced by disturbing the system infinitesimally from a position of stable equilibrium and leaving it to itself. Thus we may make a gyrostatic system such that it is in equilibrium under the influence of certain positive forces applied to different points of this system; all the forces being precisely the same as, and the points of application similarly situated to, those of the stable system with springs. Then, provided proper masses (that is to say, proper amounts and distributions of inertia) be attributed to the links, we may remove the external forces from each system, and the consequent vibration of the points of application of the forces will be identical. Or we may act upon the systems of material points and springs with any given forces for any given time, and leave it to itself, and do the same thing for the gyrostatic system; the consequent motion will be the same in the two cases. If in the one case the springs are made more and more stiff, and in the other case the angular velocities of the fly-wheels are made greater and greater, the periods of the vibrational constituents of the motion will become shorter and shorter, and the amplitudes smaller and smaller, and the motions will approach more and more nearly those of two perfectly rigid groups of material points, moving through space and rotating according to the well-known mode of rotation of a rigid body having unequal moments of inertia about its three principal axes. In one case the ideal nearly rigid connection between the particles is produced by massless exceedingly stiff springs; in the other case it is produced by the exceedingly rapid rotation of the fly-wheels in a system which, when the fly-wheels are deprived of their rotation, is perfectly limp.

The drawings (Figs. 1 and 2) before you illustrate two such material systems.[1] The directions of rotation of the fly-wheels in the gyrostatic system (Fig. 2) are indicated by directional ellipses, which show in perspective the direction of rotation of the fly-wheel of each gyrostat. The gyrostatic system (Fig. 2) might have been constituted of two gyrostatic members, but four are shown for symmetry. The inclosing circle represents in each case in section an inclosing spherical shell to prevent the interior from being seen. In the inside of one there are fly-wheels, in the inside of the other a massless spring. The projecting hooked rods seem as if they are connected by a spring in each case. If we hang any one of the systems up by the hook on one of its projecting rods, and hang a weight to the hook of the other projecting rod, the weight, when first put on, will oscillate up and down, and will go on doing so for ever if the system be absolutely unfrictional. If we check the vibration by hand, the weight will hang down at rest, the pin drawn out to a certain degree; and the distance drawn out will be simply proportional to the weight hung on, as in an ordinary spring balance.

Here, then, out of matter possessing rigidity, but absolutely devoid of elasticity, we have made a perfect model of a spring in the form of a spring balance. Connect millions of millions of particles by pairs of rods such as these of this spring balance, and we have a group of particles constituting an elastic solid; exactly fulfilling the mathematical ideal worked out by Navier, Poisson, and Cauchy, and many other mathematicians who, following their example, have endeavoured to found a theory of the elasticity of solids on mutual attraction and repulsion between a group of material particles. All that can possibly be done by this theory, with its assumption of forces acting according to any assumed law of relation to distance, *is* done by the gyrostatic system. But the gyrostatic system does, besides, what the system of naturally acting material particles cannot do: it constitutes an elastic solid which can have the Faraday magneto-optic rotation of the plane of polarisation of light; supposing the application of our solid to be a model of the luminiferous ether for illustrating the undulatory theory of light. The gyrostatic model spring balance is arranged to have zero moment of momentum as a whole, and therefore to contribute nothing to the Faraday rotation; with this arrangement the model illustrates the luminiferous ether in a field unaffected by magnetic force. But now let there be a different rotational velocity imparted to the jointed square round the axis of the two projecting hooked rods, such as to give a resultant moment of momentum round any given line through the centre of inertia of the system, and let pairs of the hooked rods in the model thus altered, which is no longer a model of a mere spring balance, be applied as connections between millions of pairs of particles as before; with the lines of resultant moment of momentum all similarly directed. We now have a model elastic

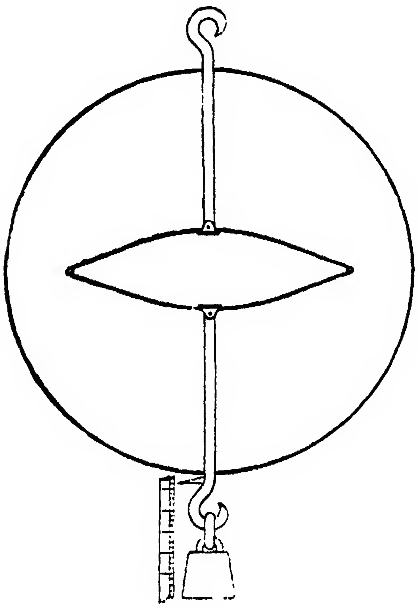


Fig. 1.

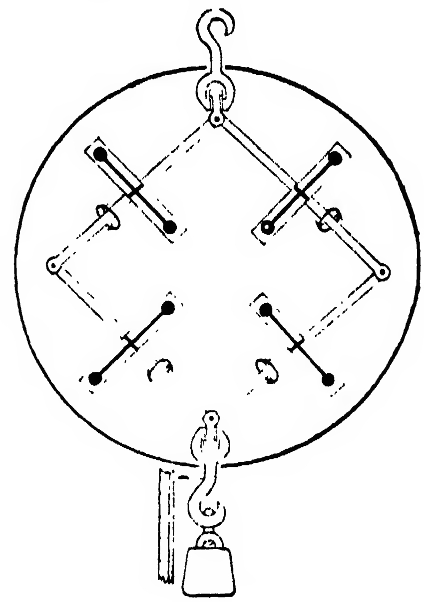

Fig. 2.

[1] In Fig. 1 the two hooked rods seen projecting from the sphere are connected by an elastic coach-spring. In Fig. 2 the hooked rods are connected one to each of two opposite corners of a four-sided jointed frame, each member of which carries a gyrostat so that the axis of rotation of the fly-wheel is in the axis of the member of the frame which bears it. Each of the hooked rods in Fig. 2 is connected to the framework through a swivel joint, so that the whole gyrostatic framework may be rotated about the axis of the hooked rods in order to annul the moment of momentum of the framework about this axis due to rotation of the fly-wheels in the gyrostat.

solid which will have the property that the direction of vibration in waves of rectilinear vibrations propagated through it shall turn round the line of propagation of the waves, just as Faraday's observation proves to be done by the line of vibration of light in a dense medium between the poles of a powerful magnet. The case of wave front perpendicular to the lines of resultant moment of momentum (that is to say, the direction of propagation being parallel to these lines) corresponds, in our mechanical model, to the case of light travelling in the direction of the lines of force in a magnetic field.

In these illustrations and models we have different portions of ideal rigid matter acting upon one another, by normal pressure at mathematical points of contact—of course no forces of friction are supposed. It is exceedingly interesting to see how thus, with no other postulates than inertia, rigidity, and mutual impenetrability, we can thoroughly model not only an elastic solid, and any combination of elastic solids, but so complex and recondite a phenomenon as the passage of polarised light through a magnetic field. But now, with the view of ultimately discarding the postulate of rigidity from all our materials, let us suppose some to be absolutely destitute of rigidity, and to possess merely inertia and incompressibility, and mutual impenetrability with reference to the still remaining rigid matter. With these postulates we can produce a perfect model of mutual action at a distance between solid particles, fulfilling the condition, so keenly desired by Newton and Faraday, of being explained by continuous action through an intervening medium. The law of the mutual force in our model, however, is not the simple Newtonian law, but the much more complex law of the mutual action between electro-magnets—with this difference, that in the hydro-kinetic model in every case the force is opposite in direction to the corresponding force in the electro-magnetic analogue. Imagine a solid bored through with a hole and placed in our ideal perfect liquid. For a moment let the hole be stopped by a diaphragm, and let an impulsive pressure be applied for an instant uniformly over the whole membrane, and then instantly let the membrane be dissolved into liquid. This action originates a motion of the liquid relatively to the solid, of a kind to which I have given the name of "irrotational circulation," which remains absolutely constant however the solid be moved through the liquid. Thus, at any time the actual motion of the liquid at any point in the neighbourhood of the solid will be the resultant of the motion it would have in virtue of the circulation alone, were the solid at rest, and the motion it would have in virtue of the motion of the solid itself, had there been no circulation established through the aperture. It is interesting and important to remark in passing that the whole kinetic energy of the liquid is the sum of the kinetic energies which it would have in the two cases separately. Now, imagine the whole liquid to be inclosed in an infinitely large, rigid, containing vessel, and in the liquid, at an infinite distance from any part of the containing vessel, let two perforated solids, with irrotational circulation through each, be placed at rest near one another. The resultant fluid motion due to the two circulations will give rise to fluid pressure on the two bodies, which, if unbalanced, will cause them to move. The force systems—force-and-torques, or pairs of forces—required to prevent them from moving will be mutual and opposite, and will be the same as, but opposite in direction to, the mutual force systems required to hold at rest two electro-magnets fulfilling the following specification. The two electro-magnets are to be of the same shape and size as the two bodies, and to be placed in the same relative positions, and to consist of infinitely thin layers of electric currents in the surfaces of solids possessing extreme diamagnetic quality—in other words, infinitely small permeability. The distribution of electric current on each body may be any whatever which fulfils the condition that the total current across any closed line drawn on the surface once through the aperture is equal to $1/4\pi$ of the circulation[1] through the aperture in the hydro-kinetic analogue.

It might be imagined that the action at a distance thus provided for by fluid motion could serve as a foundation for a theory of the equilibrium, and the vibrations, of elastic solids, and the transmission of waves like those of light through an extended quasi-elastic solid medium. But unfortunately for this idea the equilibrium is essentially unstable, both in the case of magnets, and, notwithstanding the fact that the forces are oppositely directed, in the hydro-kinetic analogue also, when the several movable bodies (two or any greater number) are so placed relatively as to be in equilibrium. If, however, we connect the perforated bodies with circulation through them in the hydro-kinetic system, by jointed rigid connecting links, we may arrange for configurations of stable equilibrium. Thus without fly-wheels, but with fluid circulations through apertures, we may make a model spring balance, or a model luminiferous ether, either without or with the rotational quality corresponding to that of the true luminiferous ether in the magnetic fluid —in short, do all by the perforated solids with circulations through them that we saw we could do by means of linked gyrostats. But something that we cannot do by linked gyrostats we can do by the perforated bodies with fluid circulation: we can make a model gas. The mutual action at a distance, repulsive or attractive according to the mutual aspect of the two bodies when passing within collisional distance[1] of one another, suffices to produce the change of direction of motion in collision, which essentially constitutes the foundation of the kinetic theory of gases, and which, as we have seen before, may as well be due to attraction as to repulsion, so far as we know from any investigation hitherto made in this theory.

There remains, however, as we have seen before, the difficulty of providing for the case of actual impacts between the solids, which must be done by giving them massless spring buffers, or, which amounts to the same thing, attributing to them repulsive forces sufficiently powerful at very short distances to absolutely prevent impacts between solid and solid; unless we adopt the equally repugnant idea of infinitely small perforated solids, with infinitely great fluid circulations through them. Were it not for this fundamental difficulty, the hydro-kinetic model gas would be exceedingly interesting; and, though we could scarcely adopt it as conceivably a true representation of what gases really are, it might still have some importance as a model configuration of solid and liquid matter, by which without elasticity the elasticity of a true gas might be represented.

But lastly, since the hydro-kinetic model gas with perforated solids and fluid circulations through them fails because of the impacts between the solids, let us annul the solids and leave the liquid performing irrotational circulation round vacancy,[2] in the place of the solid cores which we have hitherto supposed; or let us annul the rigidity of the solid cores of the rings and give them molecular rotation according to Helmholtz's theory of vortex motion. For stability the molecular rotation must be such as to give the same velocity at the boundary of the rotational fluid core as that of the irrotationally circulating liquid in contact with it, because, as I have proved, frictional slip between two portions of liquid in contact is inconsistent with stability. There is a further condition, upon which I cannot enter into detail just now, but which may be understood in a general way when I say that it is a condition of either uniform or of increasing molecular rotation from the surface inwards, analogous to the condition that the density of a liquid, resting for example under the influence of gravity, must either be uniform or must be greater below than above for stability of equilibrium. All that I have said in favour of the model vortex gas composed of perforated solids with fluid circulations through them holds without modification for the purely hydro-kinetic model, composed of either Helmholtz cored vortex-rings or of coreless vortices, and we are now troubled with no such difficulty as that of the impacts between solids. Whether, however, when the vortex theory of gases is thoroughly worked out, it will or will not be found to fail in a manner analogous to the failure which I have already pointed out in connection with the kinetic theory of gases composed of little elastic solid molecules, I cannot at present undertake to speak with certainty. It seems to me most probable that the vortex theory cannot fail in any such way, because all I have been able to find out hitherto regarding the vibration of

[1] The integral of tangential component velocity all round any closed curve, passing once through the aperture, is defined as the "cyclic constant," or the "circulation" ("Vortex Motion," § 60 (*a*), *Trans.* R. S. E. April 29, 1867). It has the same value for all closed curves passing just once through the aperture, and it remains constant through all time, whether the solid body be in motion or at rest.

[1] According to this view there is no precise distance, or definite condition respecting the distance, between two molecules, at which apparently they come to be in collision, or when receding from one another they cease to be in collision. It is convenient, however, in the kinetic theory of gases, to adopt arbitrarily a precise definition of collision, according to which two bodies or particles mutually acting at a distance may be said to be in collision when their mutual action exceeds some definite arbitrarily assigned limit, as, for example, when the radius of curvature of the path of either body is less than a stated fraction (1/100, for instance) of the distance between them.

[2] Investigations respecting coreless vortices will be found in a paper by the author, "Vibrations of a Columnar Vortex," *Proc.* R. S. E., March 1 1880; and a paper by Hicks, recently read before the Royal Society.

vortices,[1] whether cored or coreless, does not seem to imply the liability of translational or impulsive energies of the individual vortices becoming lost in energy of smaller and smaller vibrations.

As a step towards kinetic theory of matter it is certainly most interesting to remark that in the quasi-elasticity, elasticity looking like that of an india-rubber band, which we see in a vibrating smoke-ring launched from an elliptic aperture, or in two smoke-rings which were circular, but which have become deformed from circularity by mutual collision, we have in reality a virtual elasticity in matter devoid of elasticity, and even devoid of rigidity, the virtual elasticity being due to motion, and generated by the generation of motion.

SECTION B

CHEMICAL SCIENCE

OPENING ADDRESS BY PROF. SIR HENRY ENFIELD ROSCOE, PH.D., LL.D., F.R.S., F.C.S., PRESIDENT OF THE SECTION

WITH the death of Berzelius in 1848 ended a well-marked epoch in the history of our science; with that of Dumas—and, alas! that of Wurtz also—in 1884 closes a second. It may not perhaps be unprofitable on the present occasion to glance at some few points in the general progress which chemistry has made during this period, and thus to contrast the position of the science in the "sturm und drang" year of 1848, with that in the present, perhaps quieter, period.

The differences between what may probably be termed the Berzelian era and that with which the name of Dumas will for ever be associated show themselves in many ways, but in none more markedly than by the distinct views entertained as to the nature of a chemical compound.

According to the older notions, the properties of compounds are essentially governed by a qualitative nature of their constituent atoms, which were supposed to be so arranged as to form a binary system. Under the new ideas, on the other hand, it is mainly the number and arrangement of the atoms within the molecule, which regulate the characteristics of the compound which is to be looked on not as built up of two constituent groups of atoms, but as forming one group.

Amongst those who successfully worked to secure this important change of view on a fundamental question of chemical theory, the name of Dumas himself must first be mentioned, and, following upon him, the great chemical twin-brethren Laurent and Gerhardt, who, using both the arguments of test-tube and of pen in opposition to the prevailing views, gradually succeeded, though scarcely during the lifetime of the first, in convincing chemists that the condition of things could hardly be a healthy one when chemistry was truly defined "as the science of bodies which do not exist." For Berzelius, adhering to his preconceived notions, had been forced by the pressure of new discovery into the adoption of formulæ which gradually became more and more complicated, and led to more and more doubtful hypotheses, until his followers at last could barely succeed in building up the original radical from its numerous supposed component parts. Such a state of things naturally brought about its own cure, and the unitary formulæ of Gerhardt began to be generally adopted.

It was not, however, merely as an expression of the nature of the single chemical compound that this change was beneficial, but, more particularly, because it laid open the general analogies of similarly constituted compounds, and placed fact as the touchstone by which the constitution of these allied bodies should be ascertained. Indeed, Gerhardt, in 1852, gave evidence of the truth of this in his well-known theory of type, according to which, organic compounds of ascertained constitution can be arranged under the four types of hydrogen, hydrochloric acid, water, and ammonia, and of which it is, perhaps, not too much to say that it has, more than any other of its time, contributed to the clearer understanding of the relations existing amongst chemical compounds.

Another striking difference of view between the chemistry of the Berzelian era and that of what we sometimes term the modern epoch is illustrated by the so-called substitution theory. Dumas, to whom we owe this theory, showed that chlorine can take the place of hydrogen in many compounds, and that the resulting body possesses characters similar to the original. Berzelius opposed this view, insisting that the essential differences between these two elements rendered the idea of a substitution impossible, and notwithstanding the powerful advocacy of Liebig, and the discovery by Melsens of reverse substitutions (that is, the re-formation of the original compound from its substitution-product), Berzelius remained to the end unconvinced, and that which was in reality a confirmation of his own theory of compound radicals, which, as Liebig says, "illumined many a dark chapter in organic chemistry," was looked upon by him as an error of the deepest dye. This inability of many minds to see in the discoveries of others confirmation of their own views is not uncommon; thus Dalton, we may remember, could never bring himself to admit the truth of Gay-Lussac's laws of gaseous volume-combination, although, as Berzelius very truly says, if we write *atom* for *volume* and consider the substance in the solid state in place of the state of gas, the discovery of Gay-Lussac is seen to be one of the most powerful arguments in favour of Dalton's hypothesis.

But there is another change of view, dating from the commencement of the Dumas epoch, which has exerted an influence equal, if not superior, to those already named on the progress of our science. The relative weights of the ultimate particles, to use Dalton's own words, which up to this time had been generally adopted by chemists, were the equivalent weights of Dalton and Wollaston, representing, in the case of oxygen and hydrogen, the proportions in which these elements combine, viz. as 8 to 1. The great Swedish chemist at this time stood almost alone in supporting another hypothesis; for, founding his argument on the simple laws of volume-combination enunciated by Gay-Lussac, he asserted that the true atomic weights are to be represented by the relations existing between equal volumes of the two gases, viz. as 16 to 1. Still these views found no favour in the eyes of chemists until Gerhardt, in 1843, proposed to double the equivalent weights of oxygen, sulphur, and carbon, and then the opposition which this suggestion met with was most intense, Berzelius himself not even deigning to mention it in his annual account of the progress of the science, thus proving the truth of his own words: "That to hold an opinion habitually often leads to such an absolute conviction of its truth that its weak points are unregarded, and all proofs against it ignored." Nor were these views generally adopted by chemists until Cannizaro, in 1858, placed the whole subject on its present firm basis by clearly distinguishing between equivalent and molecular weights, showing how the atomic weights of the constituent elements are derived from the molecular weights of their volatile compounds based upon the law of Avogadro and Ampère, or where, as is the case with many metals, no compounds of known vapour-density exist, how the same result may be ascertained by the help of the specific heat of the element itself. Remarkable as it may appear, it is nevertheless true that it is in the country of their birth that Gerhardt's atomic weights and the consequent atomic nomenclature have met with most opposition, so much so that within a year or two of the present time there was not a single course of lectures delivered in Paris in which these were used.

The theory of organic radicals, developed by Liebig so long ago as 1834, received numerous experimental confirmations in succeeding years. Bunsen's classical research on cacodyl, proving the possibility of the existence of metallo-organic radicals capable of playing the part of a metal, and the isolation of the hydrocarbon ethyl by Frankland in 1849, laid what the supporters of the theory deemed the final stone in the structure.

The fusion of the radical and type theories, chiefly effected by the discovery in 1849 of the compound ammonias by Wurtz, brings us to the dawn of modern chemistry. Henceforward organic compounds were seen to be capable of comparison with simple inorganic bodies, and hydrogen not only capable of replacement by chlorine, or by a metal, but by an organic group or radical.

To this period my memory takes me back. Liebig at Giessen, Wöhler in Gottingen, Bunsen in Marburg, Dumas, Wurtz, and Laurent and Gerhardt in Paris, were the active spirits in Continental chemistry. In our own country, Graham, whose memorable researches on the phosphates had enabled Liebig to found his theory of polybasic acids, was working and lecturing at University College, London; and Williamson, imbued with the new doctrines and views of the twin French chemists, had just

[1] See papers by the author "On Vortex Motion," *Trans.* R. S. E., April 1867, and "Vortex Statics," *Proc.* R. S. E., December 1875; also a paper by J. J. Thomson, B.A., "On the Vibrations of a Vortex Ring," *Trans.* R. S., December 1881, and his valuable book on "Vortex Motion."

been appointed to the Chair of Practical Chemistry in the same College, vacant by the death of poor Fownes. At the same time, Hofmann, in whom Liebig found a spirit as enthusiastic in the cause of scientific progress as his own, bringing to England a good share of the Giessen fire, founded the most successful school of chemistry which this country has yet seen.

At the Edinburgh meeting of this Association in 1850, Williamson read a paper on "Results of a Research on Ætherification," which included not only a satisfactory solution of an interesting and hitherto unexplained problem, but was destined to exert a most important influence on the development of our theoretical views. For he proved, contrary to the then prevailing ideas, that ether contains twice as much carbon as alcohol, and that it is not formed from the latter by a mere separation of the elements of water, but by an exchange of hydrogen for ethyl, and this fact, being in accordance with Avogadro's law of molecular volumes, could only be represented by regarding the molecule of water as containing two atoms of hydrogen to one of oxygen, one of the former being replaced by one of ethyl to form alcohol, and the two of hydrogen by two of ethyl to form ether. Then Williamson introduced the type of water (subsequently adopted by Gerhardt) into organic chemistry, and extended our views of the analogies between alcohols and acids, by pointing out that these latter are also referable to the water-type, predicting that bodies bearing the same relations to the ordinary acids as the ethers do to the alcohols must exist, a prediction shortly afterwards (1852) verified by Gerhardt's discovery of the anhydrides. Other results followed in rapid succession, all tending to knit together the framework of modern theoretical chemistry. Of these the most important was the adoption of condensed types, of compounds constructed on the type of two and three molecules of water, with which the names of Williamson and Odling are connected, culminating in the researches of Brodie on the higher alcohols, of Berthelot on glycerine, and of Wurtz on the dibasic alcohols or glycols; whilst, in another direction, the researches of Hofmann on the compound amines and amides opened out an entirely new field, showing that either a part or the whole of the hydrogen in ammonia can be replaced by other elements or elementary groups without the type losing its characteristic properties.

Again, in 1852, we note the first germs of a theory which was destined to play an all-important part in the progress of the science, viz., the doctrine of valency or atomicity, and to Frankland it is that we owe this new departure. Singularly enough, whilst considering the symmetry of construction visible amongst the inorganic compounds of nitrogen, phosphorus, arsenic, and antimony, and whilst putting forward the fact that the combining power of the attracting element is always satisfied by the same number of atoms, he does not point out the characteristic tetrad nature of carbon; and it was not until 1858 that Couper initiated, and Kekulé, in the same year, thoroughly established, the doctrine of the linking of the tetrad carbon atoms, a doctrine to which, more than to any other, is due the extraordinary progress which organic chemistry has made during the last twenty years, a progress so vast that it is already found impossible for one individual, even though he devote his whole time and energies to the task, to master all the details, or make himself at home with the increasing mass of new facts which the busy workers in this field are daily bringing forth.

The subject of the valency of the elements is one which, since the year above referred to, has given chemists much food for discussion, as well as opportunity for experimental work. But whether we range ourselves with Kekulé, who supports the unalterable character of the valency of each element, or with Frankland, who insists on its variability, it is now clear to most chemists that the hard and fast lines upon which this theory was supposed to stand cannot be held to be secure. For if the progress of investigation has shown that it is impossible in many instances to affix one valency to an element which forms a large number of different compounds, it is also equally impossible to look on the opposite view as tending towards progress, inasmuch as to ascribe to an element as many valencies as it possesses compounds with some other element, is only expressing by circuitous methods what the old Daltonian law of combination in multiple proportion states in simple terms. Still we may note certain generally-accepted conclusions: in the first place, that of the existence of non-saturated compounds both inorganic and organic, as carbon-monoxide on the one hand, and malic and citraconic acids on the other. Secondly, that the valency of an element is not only dependent upon the nature of the element with which it combines, but that this valency is a periodic function of the atomic weight of the other component. Thus the elements of the chlorine group are always monads when combined with positive elements or radicals, but triad, pentad, and heptad with negative ones. Again, the elements of the sulphur group are dyads in the first case, but tetrad and hexad in the second. The periodicity of this property of the atoms, increasing and again diminishing, is clearly seen in such a series as

$$AgCl_1, CdCl_2, InCl_3, SnCl_4, SbH_3, TeH_2, IH,$$

as well as in the series of oxides. The difficulties which beset this subject may be judged of by the mention of a case or two:—Is vanadium a tetrad because its highest chloride contains four atoms of chlorine? What are we to say is the valency of lead when one atom unites with four methyls to form a volatile product, and yet the vapour-density of the chloride shows that the molecule contains one of metal to two of chlorine? Or, how can our method be said to determine the valency of tungsten when the hexachloride decomposes in the state of vapour, and the pentachloride is the highest volatile stable compound? How again are we to define the point at which a body is volatile without decomposition?—thus sulphur tetrachloride, one of the most unstable of compounds, can be vaporised without decomposition at all temperatures below $-22°$, whilst water, one of the most stable of known compounds, is dissociated into its elements at the temperature of melting platinum.

But, however many doubts may have been raised in special instances against a thorough application of the law of valency, it cannot be denied that the general relations of the elements which this question of valency has been the means of bringing to light are of the highest importance, and point to the existence of laws of Nature of the widest significance; I allude to the periodic law of the elements first foreshadowed by Newlands, but fully developed by Mendeléeff and Lothar Meyer. Guided by the principle that the chemical properties of the elements are a periodic function of their atomic weights, or that matter becomes endowed with analogous properties when the atomic weight of an element is increased by the same or nearly the same number, we find ourselves for the first time in possession of a key which enables us to arrange the hitherto *disjecta membra* of our chemical household in something like order, and thus gives us means of indicating the family resemblances by which these elements are characterised.

And here we may congratulate ourselves on the fact that, by the recent experiments of Brauner, and of Nilson and Pettersen respectively, tellurium and beryllium, two of the hitherto outstanding members, have been induced to join the ranks, so that at the present time osmium is the only important defaulter amongst the sixty-four elements, and few persons will doubt that a little careful attention to this case will remove the stigma which yet attaches to its name. But this periodic law makes it possible for us to do more; for as the astronomer, by the perturbations of known planets, can predict the existence of hitherto unknown ones, so the chemist, though, of course, with much less satisfactory means, has been able to predict with precision the properties, physical and chemical, of certain missing links amongst the elements, such as ekaluminium and ekaboron, then unborn, but which shortly afterwards became well known to us in the flesh as gallium and scandium. We must, however, take care that success in a few cases does not blind us to the fact that the law of Nature which expresses the relation between the properties of the elements and the value of the atomic weights is as yet unknown; that many of the groupings are not due to any well-ascertained analogy of properties of the elements, and that it is only because the values of their atomic weights exhibit certain regularities that such a grouping is rendered possible. So, to quote Lothar Meyer, we shall do well in this, as indeed in all similar cases in science, to remember the danger pointed out in Bacon's aphorism, that "The mind delights in springing up to the most general axioms, that it may find rest, but after a short stay here it disdains experience," and to bear in mind that it is only the lawful union of hypothesis with experiment which will prove a fruitful one in the establishment of a systematic inorganic chemistry which need not fear comparison with the order which reigns in the organic branch of our science. And here it is well to be reminded that complexity of constitution is not the sole prerogative of the carbon compounds, and that before this systematisation of inorganic chemistry can be effected we shall have to come to terms with many compounds concerning whose constitution we are at present wholly in ignorance. As instances

of such I would refer to the finely crystalline phospho-molybdates, containing several hundred atoms in the molecule, lately prepared by Wolcott Gibbs.

Arising out of Kekulé's theory of the tetrad nature of the carbon atom, came the questions which have caused much debate among chemists: (1) Are the four combining units of the carbon atom of equal value or not? and (2) Is the assumption of a dyad carbon atom in the so-called non-saturated compounds justifiable or not? The answer to the first of these, a favourite view of Kolbe's, is given in the now well-ascertained laws of isomerism; and from the year 1862, when Schorlemmer proved the identity of the hydrides of the alcohol radicals with the so-called radicals themselves, this question may be said to have been set at rest: for Lossen himself admits that the existence of his singular isomeric hydroxylamine derivatives can be explained otherwise than by the assumption of a difference between each of the combining units of nitrogen, and the differences supposed by Schreiner to hold good between the methyl-ethyl carbonic ethers have been shown to have no existence in fact. With respect to the second point the reply is no less definite, and is recorded in the fact, amongst others, that ethylene chlorhydrin yields on oxidation chloracetic acid, a reaction which cannot be explained on the hypothesis of the existence in ethylene of a dyad carbon atom.

Passing from this subject, we arrive, by a process of natural selection, at more complicated cases of chemical orientation—that is, given certain compounds which possess the same composition and molecular formulæ but varying properties, to find the difference in molecular structure by which such variation of properties is determined. Problems of this nature can now be satisfactorily solved, the number of possible isomers foretold, and this prediction confirmed by experiment. The general method adopted in such an experimental inquiry into the molecular arrangement or chemical constitution of a given compound is either to build up the structure from less complicated ones of known constitution, or to resolve it into such component parts. Thus, for example, if we wish to discriminate between several isomeric alcohols, distinguishing the ordinary or primary class from the secondary or tertiary class, the existence of which was predicted by Kolbe in 1862, and of which the first member was prepared by Friedel in 1864, we have to study their products of oxidation. If one yields an acid having the same number of carbon atoms as the alcohol, it belongs to the first class and possesses a definite molecular structure; if it splits up into two distinct carbon compounds, it is a secondary alcohol; and if three carbon compounds result from its oxidation, it must be classed in the third category, and to it belongs a definite molecular structure, different from that of the other two.

In a similar way orientation in the much more complicated aromatic hydrocarbons can be effected. This class of bodies forms the nucleus of an enormous number of carbon compounds which, both from a theoretical and a practical point of view, are of the highest interest. For these bodies exhibit characters and possess a constitution totally different from those of the so-called fatty substances, the carbon atoms being linked together more intimately than is the case in the latter-named group of bodies. Amongst them are found all the artificial colouring matters, and some of the most valuable pharmaceutical and therapeutical agents.

The discovery of the aniline colours by Perkin, their elaboration by Hofmann, the synthesis of alizarin by Graebe and Liebermann, being the first vegetable colouring matter which has been artificially obtained, the artificial production of indigo by Baeyer, and lastly the preparation, by Fischer, of kairin, a febrifuge as potent as quinine, are some of the well-known recent triumphs of modern synthetical chemistry. And these triumphs, let us remember, have not been obtained by any such "random haphazarding" as yielded results in Priestley's time. In the virgin soil of a century ago, the ground only required to be scratched and the seed thrown in to yield a fruitful crop; now the surface soil has long been exhausted, and the successful cultivator can only obtain results by a deep and thorough preparation, and by a systematic and scientific treatment of his material.

In no department of our science has the progress made been more important than in that concerned with the accurate determination of the numerical, physical, and chemical constants upon the exactitude of which every quantitative chemical operation depends. For the foundation of an accurate knowledge of the first of these constants, viz., the atomic weights of the elements, science is indebted to the indefatigable labours of Berzelius. But "humanum est errare," and even Berzelius's accurate hand and delicate conscientiousness did not preserve him from mistakes, since corrected by other workers. In such determinations it it difficult, if not impossible, always to ascertain the limits of error attaching to the number. The errors may be due in the first place to manipulative faults, in the second to inaccuracy of the methods, or lastly to mistaken views as to the composition of the material operated upon; and hence the uniformity of any series of similar determinations gives no guarantee of their truth, the only safe guide being the agreement of determinations made by altogether different methods. The work commenced by Berzelius has been worthily continued by many chemists. Stas and Marignac, bringing work of an almost astronomical accuracy into our science, have ascertained the atomic weights of silver and iodine to within one hundred-thousandth of their value, whilst the numbers for chlorine, bromine, potassium, sodium, nitrogen, sulphur, and oxygen may now be considered correct to within a unit in the fourth figure. Few of the elements, however, boast numbers approaching this degree of accuracy, and many may even still be erroneous from half to a whole unit of hydrogen. And, as Lothar Meyer says, until the greater number of the atomic weights are determined to within one or two tenths of the unit, we cannot expect to be able to ascertain the laws which certainly govern these numbers, or to recognise the relations which undoubtedly exist between them and the general chemical and physical properties of the elements. Amongst the most interesting recent additions to our knowledge made in this department we may note the classical experiments, in 1880, of J. W. Mallet on aluminium, and in the same year of J. P. Cooke on antimony, and those, in the present year, of Thorpe on titanium.

Since the date of Berzelius's death to the present day, no discovery in our science has been so far-reaching, or led to such unforeseen and remarkable conclusions, as the foundation of Spectrum Analysis by Bunsen and Kirchhoff in 1860.

Independently altogether of the knowledge which has been gained concerning the distribution of the elementary bodies in terrestrial matter, and of the discovery of half a dozen new elements by its means, and putting aside for a moment the revelation of a chemistry not bounded by this world, but limitless as the heavens, we find that over and above all these results spectrum analysis offers the means, not otherwise open to us, of obtaining knowledge concerning the atomic and molecular condition of matter.

Let me recall some of the more remarkable conclusions to which the researches of Lockyer, Schuster, Liveing and Dewar, Wüllner, and others in this direction have led. In the first place it is well to bear in mind that a difference of a very marked kind, first distinctly pointed out by Alex. Mitscherlich, is to be observed between the spectrum of an element and that of its compounds, the latter only being seen in cases in which the compound is not dissociated at temperatures necessary to give rise to a glowing gas. Secondly, that these compound spectra—as, for instance, those of the halogen compounds of the alkaline-earth metals—exhibit a certain family likeness, and show signs of systematic variation in the position of the lines, corresponding to changes in the molecular weight of the vibrating system. Still this important subject of the relation of the spectra of different elements is far from being placed on a satisfactory basis, and in spite of the researches of Lecoq de Boisbaudran, Ditte, Troost and Hautefeuille, Ciamician, and others, it cannot be said that as yet definite proof has been given in support of the theory that a causal connection is to be found between the emission spectra of the several elements belonging to allied groups and their atomic weights or other chemical or physical properties. In certain of the single elements, however, the connection between the spectra and the molecular constitution can be traced. In the case of sulphur, for example, three distinct spectra are known. The first of these, a continuous one, is exhibited at temperatures below 500°, when, as we know from Dumas' experiments, the density of the vapour is three times the normal, showing that at this temperature the molecule consists of six atoms. The second spectrum is seen when the temperature is raised to above 1000°, when, as Deville and Troost have shown, the vapour reaches its normal density, and the molecule of sulphur, as with most other gases, contains two atoms, and this is a band spectrum, or one characterised by channelled spaces. Together with this band spectrum, and especially round the negative pole, a spectrum of bright lines is observed. This latter is doubtless due to the vibrations of the single atoms of the dissociated molecule, the

existence of traces of a band spectrum demonstrating the fact that in some parts of the discharge the tension of dissociation is insufficient to prevent the reunion of the atoms to form the molecule.

To this instance of the light thrown on molecular relations by changes in the spectra, others may be added. Thus the low-temperature spectrum of channelled spaces, mapped by Schuster and myself, in the case of potassium, corresponds to the molecule of two atoms and to the vapour-density of seventy-nine, as observed by Dewar and Dittmar. Again, both oxygen and nitrogen exhibit two, if not three, distinct spectra: of these the line spectrum seen at the highest temperatures corresponds to the atom; the band spectrum seen at intermediate temperatures represents the molecule of two atoms; whilst that observed at a still lower point would, as in the case of sulphur, indicate the existence of a more complicated molecule, known to us in one instance as ozone.

That this explanation of the cause of these different spectra of an element is the true one, can be verified in a remarkable way. Contrary to the general rule amongst those elements which can readily be volatilised, and with which, therefore, low-temperature spectra can be studied, mercury exhibits but one spectrum, and that one of bright lines, or, according to the preceding theory, a spectrum of atoms. So that, judging from spectroscopic evidence, we infer that the atoms of mercury do not unite to form a molecule, and we should predict that the vapour-density of mercury is only half its atomic weight. Such we know, from chemical evidence, is really the case, the molecule of mercury being identical in weight with its atom.

The cases of cadmium and iodine require further elucidation. The molecule of gaseous cadmium, like that of mercury, consists of one atom; probably, therefore, the cadmium spectrum is also distinguished by one set of lines. Again, the molecule of iodine at 1200° separates, as we know from Victor Meyer's researches, into single atoms. Here spectrum analysis may come again to our aid; but, as Schuster remarks, in his report on the spectra of the non-metallic elements, a more extensive series of experiments than those already made by Ciamician is required before any definite opinion as to the connection of the different iodine spectra with the molecular condition of the gas can be expressed.

It is not to be wondered at that these relations are only exhibited in the case of a few elements. For most of the metals the vapour-density remains, and probably will remain, an unknown quantity, and therefore the connection between any observed changes in the spectra and the molecular weights must also remain unknown. The remarkable changes which the emission spectrum of a single element—iron, for instance—exhibits have been the subject of much discussion, experimental and otherwise. Of these, the phenomenon of long and short lines is one of the most striking, and the explanation that the long lines are those of low temperature appears to meet the fact satisfactorily, although the effect of dilution, that is, a reduction of the quantity of material undergoing volatilisation, is, remarkably enough, the same as that of diminution of temperature. Thus it is possible, by the examination of a spectrum by Lockyer's method, to predict the changes which it will undergo, either on alteration of temperature, or by an increase or decrease of quantity. There appears to be no theoretical difficulty in assuming that the relative intensity of the lines may vary when the temperature is altered, and the molecular theory of gases furnishes us with a plausible explanation of the corresponding change when the relative quantities of the luminous elements in a mixture are altered. Lockyer has proposed a different explanation of the facts. According to him, every change of relative intensity means a corresponding change of molecular complexity, and the lines which we see strong near the poles would bear the same relation to those which are visible throughout the field, as a line spectrum bears to a band spectrum; but then almost every line must be due to a different molecular grouping, a conclusion which is scarcely capable of being upheld without very cogent proof.

The examination of the absorption-spectra of salts, saline and organic liquids, first by Gladstone, and afterwards by Bunsen, and by Russell, as well as by Hartley for the ultra-violet, and by Abney and Festing for the infra-red region, have led to interesting results in relation to molecular chemistry. Thus Hartley finds that, in some of the more complicated aromatic compounds, definite absorption-bands in the more refrangible region are only produced by substances in which three pairs of carbon atoms are doubly linked, as in the benzene ring, and thus the means of ascertaining this double linkage is given. The most remarkable results obtained by Abney and Festing show that the radical of an organic body is always represented by certain well-marked absorption-bands, differing, however, in position, according as it is linked with hydrogen, a halogen, or with carbon, oxygen, or nitrogen. Indeed, these experimenters go so far as to say that it is highly probable that by this delicate mode of analysis the hypothetical position of any hydrogen which is replaced may be identified, thus pointing out a method of physical orientation of which, if confirmed by other observers, chemists will not be slow to avail themselves. This result, it is interesting to learn, has been rendered more than probable by the recent important researches of Perkin on the connection between the constitution and the optical properties of chemical compound.

One of the noteworthy features of chemical progress is the interest taken by physicists in fundamental questions of our science. We all remember, in the first place, Sir William Thomson's interesting speculations, founded upon physical phenomena, respecting the probable size of the atom, viz. "that if a drop of water were magnified to the size of the earth, the constituent atoms would be larger than small shot, but smaller than cricket balls." Again, Helmholtz, in the Faraday Lecture, delivered in 1881, discusses the relation of electricity and chemical energy, and points out that Faraday's law of electrolysis, and the modern theory of valency, are both expressions of the fact that, when the same quantity of electricity passes through an electrolyte, it always either sets free, or transfers to other combinations, the same number of units of affinity at both electrodes. Helmholtz further argues that, if we accept the Daltonian atomic hypothesis, we cannot avoid the conclusion that electricity, both positive and negative, is divided into elementary portions which behave like atoms of electricity. He also shows that these charges of atomic electricity are enormously large as compared, for example, with the attraction of gravitation between the same atoms; in the case of oxygen and hydrogen, 71,000 billion times larger.

A further subject of interest to chemists is the theory of the vortex-ring constitution of matter thrown out by Sir William Thomson, and lately worked out from a chemical point of view by J. J. Thomson, of Cambridge. He finds that if one such ring be supposed to constitute the most simple form of matter, say the monad hydrogen atom, then two such rings must, on coming into contact with nearly the same velocity, remain enchained together, constituting what we know as the molecule of free hydrogen. So, in like manner, systems containing two, three, and four such rings constitute the dyad, tryad, and tetrad atoms. How far this mathematical expression of chemical theory may prove consistent with fact remains to be seen.

Another branch of our science which has recently attracted much experimental attention is that of thermo-chemistry, a subject upon which in the future the foundation of dynamical chemistry must rest, and one which already proclaims the truth of the great principle of the conservation of energy in all cases of chemical as well as of physical change. But here, although the materials hitherto collected are of very considerable amount and value, the time has not yet arrived for expressing these results in general terms, and we must, therefore, be content to note progress in special lines and wait for the expansion into wider areas. Reference may, however, be properly made to one interesting observation of general significance. It is well known that, while, in most instances, the act of combination is accompanied by evolution of heat—that is, whilst the potential energy of most combining bodies is greater than that of most compounds—cases occur in which the reverse of this is true, and heat is absorbed in combination. In such cases the compound readily undergoes decomposition, frequently suddenly and with explosion. Acetylene and cyanogen seem to be exceptions to this rule, inasmuch as, whilst their component elements require to have energy added to them in order to enable them to combine, the compounds appear to be very stable bodies. Berthelot has explained this enigma by showing that, just as we may ignite a mass of dynamite without danger, whilst explosion takes place if we agitate the molecules by a detonator, so acetylene and cyanogen burn, as we know, quietly when ignited, but when their molecules are shaken by the detonation of even a minute quantity of fulminate, the constituents fly apart with explosive violence, carbon and hydrogen, or carbon and nitrogen, being set free, and the quantity of heat absorbed in the act of combination being suddenly liberated.

In conclusion, whilst far from proposing even to mention all the important steps by which our science has advanced since the year 1848, I cannot refrain from referring to two more. In the first place, to that discovery, more than foreshadowed by Faraday, of the liquefaction of the so-called permanent gases by Pictet and Cailletet; and secondly, to that of the laws of dissociation as investigated by Deville. The former, including Andrews's discovery of the critical point, indicates a connection, long unseen, between the liquid and the gaseous states of matter; the latter has opened out entirely fresh fields for research, and has given us new views concerning the stability of chemical compounds of great importance and interest.

Turning for a moment to another topic, we feel that, although science knows no nationalities, it is impossible for those who, like ourselves, exhibit strong national traits, to avoid asking whether we Anglo-Saxons hold our own, as compared with other nations, in the part we have played and are playing in the development of our science. With regard to the past, the names of Boyle, Cavendish, Priestley, Dalton, Black, Davy, are sufficient guarantees that the English have, to say the least, occupied a position second to none in the early annals of chemistry. How has it been in the era which I have attempted to describe? What is the present position of English chemistry, and what its look-out for the future? In endeavouring to make this estimate, I would take the widest ground, including not only the efforts made to extend the boundaries of our science by new discovery, both in the theoretical and applied branches, but also those which have the no less important aims of spreading the knowledge of the subject amongst the people, and of establishing industries dependent on chemical principles by which the human race is benefited. Taking this wide view, I think we may, without hesitation, affirm that the progress which chemistry has made through the energies of the Anglo-Saxon race is not less than that made by any other nation.

In so far as pure science is concerned, I have already given evidence of the not inconsiderable part which English chemists have played in the progress since 1848. We must, however, acknowledge that the number of original chemical papers now published in our language is much smaller than that appearing in the German tongue, and that the activity and devotion displayed in this direction by the heads of German laboratories may well be laid to heart by some of us in England; yet, on the other hand, it must be remembered that the circumstances of different countries are so different that it is by no means clear that we should follow the same lines. Indeed our national characteristics forbid us to do so, and it may be that the bent of the Germanic lies in the assiduous collection of facts, whilst their subsequent elaboration and connection is the natural work of our own race.

As regards the publication of so-called original work by students, and speaking now only for myself as the director of an English chemical laboratory, I feel I am doing the best for the young men who, wishing to become either scientific or industrial chemists, are placed under my charge, in giving them as sound and extensive a foundation in the theory and practice of chemical science as their time and abilities will allow, rather than forcing them prematurely into the preparation of a new series of homologous compounds or the investigation of some special reaction, or of some possible new colouring matter, though such work might doubtless lead to publication. My aim has been to prepare a young man, by a careful and fairly complete general training, to fill with intelligence and success a post either as teacher or industrial chemist, rather than to turn out mere specialists, who, placed under other conditions than those to which they have been accustomed, are unable to get out of the narrow groove in which they have been trained. And this seems a reasonable course, for whilst the market for the pure specialist, as the colour chemist for example, may easily be overstocked, the man of all-round intelligence will always find opportunity for the exercise of his powers. Far, however, from underrating the educational advantages of working at original subjects, I consider this sort of training to be of the highest and best kind, but only useful when founded upon a sound and general basis.

The difficulty which the English teacher of chemistry—and in this I may include Canada and the United States—has to contend against is that, whilst in Germany the value of this high and thorough training is generally admitted, in England a belief in its efficacy is as yet not generally entertained. "The Englishman," to quote from the recent Report of the Royal Commission on Technical Instruction, "is accustomed to seek for an immediate return, and has yet to learn that an extended and systematic education, up to and including the methods of original research, is now a necessary preliminary to the fullest development of industry, and it is to the gradual but sure growth of public opinion in this direction that we must look for the means of securing to this country in the future, as in the past, the highest position as an industrial nation."

If, in the second place, we consider the influence which Englishmen have exerted on the teaching of our science, we shall feel reason for satisfaction; many of our text-books are translated into every European language and largely used abroad; often to the exclusion of those written by Continental chemists.

Again, science teaching, both practical and theoretical, in our elementary and many secondary schools, is certainly not inferior to that in schools of similar grade abroad, and the interest in and desire for scientific training is rapidly spreading throughout our working population, and is even now as great as, if not greater than, abroad. The universities and higher colleges are also moving to take their share of the work which has hitherto been far less completely done in our country than on the continent of Europe, especially in Germany, where the healthful spirit of competition, fostered by the numerous State-supported institutions, is much more common than with us, and, being of equal value in educational as in professional or commercial matters, has had its due effect.

Turning lastly to the practical applications of our science, in what department does England not excel? and in which has she not made the most important new departures? Even in colour chemistry, concerning which we have heard, with truth, much of German supremacy, we must remember that the industry is originally an English one, as the names of Perkin and of Maule, Simpson and Nicholson, testify; and if we have hitherto been beaten hollow in the development of this branch, signs are not wanting that this may not always be the case. But take any other branch of applied chemistry, the alkali trade for instance, what names but English, with the two great exceptions of Leblanc and Solvay, do we find in connection with real discoveries? In the application of chemistry to metallurgical processes, too, the names of Darby, Cort, Neilson, and Bell in iron, of Bessemer, Thomas, Gilchrist, and Snelus in steel, of Elkington and Matthey in the noble metals, show that in these branches the discoveries which have revolutionised processes have been made by Englishmen; whilst Young, the father of paraffin, Spence the alum-maker, and Abel of gun-cotton fame, are some amongst many of our countrymen whose names may be honourably mentioned as having founded new chemical industries.

Hence, whilst there is much to stimulate us to action in the energy and zeal shown by our Continental brethren in the pursuit both of pure and applied chemistry, there is nothing to lead us to think that that the chemistry of the English-speaking nations in the next fifty years will be less worthy than that of the past half-century of standing side by side with that of her friendly rivals elsewhere.

SECTION D

BIOLOGY

OPENING ADDRESS BY H. N. MOSELEY, M.A., F.R.S., LINACRE PROFESSOR OF HUMAN AND COMPARATIVE ANATOMY IN THE UNIVERSITY OF OXFORD, PRESIDENT OF THE SECTION

IN appointing the phenomena of pelagic and deep-sea life as one of the subjects specially selected for consideration at the present meeting of this Section, the Organising Committee have, I think, done wisely. Our knowledge of the subject is at present in most active progress. It is one of the widest and deepest interest to the physiologist as well as the zoologist, and in some features claims a share of attention from the botanist. And the proximity here of the United States, to which science is indebted for so many important discoveries on deep-sea matters, is a strong argument in favour of the subject being brought forward at a British Association meeting on this side of the Atlantic. I have naturally been led to choose the consideration of some deep-sea biological questions as the subject of my address by the special interest which I have been led to take in deep-sea phenomena generally, owing to my long participation in actual deep-sea research during the voyage of H.M.S. *Challenger*.

Unfortunately, the physiology of deep-sea life has until lately

received but little attention from professed physiologists. No physiologist has, as far as I am aware, as yet set forth comprehensively and dwelt upon the numerous difficulties which are encountered when the attempt is made to comprehend the mode in which the ordinary physiological processes of Vertebrata and other animals are carried on under the peculiar physical conditions which exist at great depths.

Whilst I was on the *Challenger* voyage, absorbed principally in the zoological discoveries daily resulting from the dredging operations, I received a letter from my revered teacher, Prof. Ludwig, of Leipzig, which brought deep-sea phenomena before me in a very different light. The Professor naturally regarded deep-sea questions mainly from a physiological point of view, and asked a series of most suggestive questions bearing on it. I am much indebted to him for this and recent letters on the same subject. One of the first questions he asked was, naturally, as to the amount of oxygen present in deep-sea water. A knowledge of the conditions under which gases occur in a state of absorption in the ocean-waters is of primary importance to the physiologist. With regard to this subject, most valuable information is contained in the report by the distinguished chemist, Prof. Dittmar, on "Researches into the Composition of the Ocean-Water collected by H.M.S. *Challenger*," which has appeared during the present year, and which embody Mr. J. Y. Buchanan's results.[1] It appears from his results that, contrary to what was before suspected, the presence of free carbonic acid in sea-water is an exception. What carbonic acid is present occurs as a bicarbonate, in general more or less incompletely saturated. In surface-waters the proportion of carbonic acid increases when the temperature falls, and *vice versâ*. Deep-sea water does not contain an abnormal proportion of loose or free carbonic acid.

Hence, with regard to Mr. John Murray's interesting discovery that after certain depths are reached *Pteropod* shells are dissolved and disappear from the sea-bottom, and at certain further depths *Globigerina* shells suffer the same fate, Prof. Dittmar holds the opinion that the solution is not due to the presence of free acid, but to the solvent action of the sea-water itself, which will, even when alkaline, take up additional carbonate of lime if sufficient time be given. Thus the amount of carbonic acid normally present throughout the ocean cannot be inimical to life; but, according to the Professor, there must be in the depths of the ocean numerous bodies of richly carbonated water, for he regards the principal supply of carbonic acid to the sea-water as derived from volcanic springs and discharges issuing from the ocean-bed, the quantity derived from the decay of marine plants and animals being insignificant in comparison with this. Possibly the *Challenger*, when it dredged from deep water off the Azores immense quantities of dead and blackened coral, encountered an area which had thus been visited by a carbonic acid discharge.

With regard to the absorbed oxygen and nitrogen, the theoretical maximum quantity of oxygen absorbed at normal surface-pressure by a litre of sea-water should range, according to Prof. Dittmar's experiments and calculations, from 8·18 c.c. in cold regions at 0° C. to 4·50 c.c. in the tropics, with a temperature of 30° C. The result experimentally obtained from samples of surface-water collected during the voyage differ considerably in detail from the calculated estimates, from various causes explained, and especially because of the reduction of the amount of oxygen by oxidation and respiration. The main and almost sole source of the nitrogen and oxygen present in deep-sea water lies in the atmosphere, and is absorbed there, its quantity being thus dependent on surface conditions of temperature and pressure, and not those of the depths. A given quantity of water, having absorbed its oxygen and nitrogen at the surface, may be supposed to sink unmixed with surrounding water to the depths. During the process its amount of contained nitrogen remains constant, whilst its oxygen-supply becomes gradually diminished, owing to the process of oxidation, which in the depths goes on without compensation. That the amount of absorbed oxygen present in sea-water diminishes with the depth has been shown already by Dr. Lant Carpenter's experiments. It is not yet possible to formulate in any precise terms the relation between the depth and the diminution of the oxygen present, but Mr. J. Y. Buchanan's previous conclusion that a minimum of oxygen is attained at a depth of about 800 fathoms is not confirmed by the summing-up of the whole of the evidence now available. This result is not without biological significance, since the existence of this supposed zone with a minimum of oxygen has been used as an argument in favour of the occurrence of especially abundant life at this depth below the ocean-surface.

Prof. Dittmar finds that there is nothing characteristic of bottom-waters as such in regard to their absorbed gases, nothing to distinguish them from waters from intermediate depths. This, it seems to me, is not quite what might have been expected, as the concentration of the food-supply, and consequently of life, on the actual bottom might have led to a different result.

If there were absolute stagnation of the water at great depths, the oxygen might be reduced there to zero, but the fact that in no case has oxygen been entirely absent from any sample of deep-sea water examined proves that a certain motion and change must occur. The smallest amount of oxygen found at all was in a sample of water from a depth of 2,875 fathoms, and amounted to 0·65 c.c. per litre only, a result long ago published by Mr. Buchanan. Even this, however, may well be sufficient to support life, since Humboldt and Provencal[1] found that certain fish could breathe in water containing only one-third of that quantity of oxygen per litre. In another sample, from 1645 fathoms, it was 2·04 c.c. On the other hand, as much as 4·055 c.c. was found in a sample from 4575 fathoms, and 4·39 c.c. in one from 3025. Most remarkable, in one instance water from a depth of only 300 fathoms yielded only 1·65 c.c. of oxygen. Prof. Dittmar admits that there was no lack of anomalous results, some, no doubt, due to some extent to imperfection in the apparatus employed in collecting the water.

In connection with the valuable investigations carried on in the *Travailleur* and the *Talisman* by Prof. Milne-Edwards and his associates, French physiologists have lately commenced researches on some of the problems of deep-sea life.

Experiments have been made by M. Regnard[2] with a view of determining the effects of high pressures, corresponding with those of the deep sea, on various organisms. Yeast, after being exposed to a pressure of 1000 atmospheres, equal to a depth of about 6500 fathoms of sea-water, for an hour, was mixed with a solution of sugar. An hour elapsed before any signs of fermentation appeared, and a mixture of yeast and sugar solution did not ferment at all whilst under a pressure of 600 atmospheres, equal to a depth of about 3900 fathoms. Algæ, seeds of phanerogamic plants, Infusoria, and even Mollusca and leeches, were found to be thrown into a sort of state of sleep or latency by exposure to similar pressures, recovering from this condition after a shorter or longer period of return to normal conditions. A fish without a swimming bladder, or one with the bladder emptied of air, may be submitted to a pressure of 100 atmospheres, equivalent to a depth of 650 fathoms, without injurious effect. At 200 atmospheres, equivalent to a depth of 1300 fathoms, it becomes torpid, but soon revives when the pressure is removed. At 300 atmospheres, equivalent to a depth of about 2000 fathoms, the fish dies.

These experiments are of the highest interest. The pressure made use of was obtained by means of water in the absence of air other than that absorbed at the normal atmosphere pressure, and thus the physical conditions produced were closely similar to those actually existent in the deep sea. They are the first of their kind.

Prof. Paul Bert's[3] somewhat similar experiments related to a different question altogether—namely, the effect on aquatic organisms of water subjected to the pressure of compressed air. He found that young eels were rapidly killed when subjected to a pressure of only 15 atmospheres, and could not survive one of even 7 atmospheres for any considerable time.[4] He pointed out the essential difference between the conditions produced in such experiments and those existing in the deep sea, where the charge of oxygen contained by the water has been taken up at the surface at a pressure of one atmosphere only.

In the experiments on animals made by M. Regnard's method there is the obvious difficulty that the supply of oxygen in the water compressed cannot be renewed during the experiment but must be gradually reduced by respiration, and for this reason it would probably be useless, unless a large quantity of water would

3 [illegible] *Pression barométrique*. Paris, 1878, p. 814. 4 *Ibid*. p. 1151.

be employed, to try the effect on a fish of a very gradual application of pressure, extending over many hours. It is probable that the results would be greatly modified if plenty of time could be given for the fish to accommodate itself to the change of pressure, and the conditions in which it moves in nature slowly from one depth to another be imitated. The results of M. Regnard's further experiments will be looked forward to with great interest.

A question of the utmost moment, and one that has received a good deal of attention, is that as to the source of food of the deep-sea animals. Certainly a large proportion of this food is derived from the life on the ocean-surface. The debris of pelagic animals sinks slowly downwards, forming on its passage a sparsely scattered supply of food for any animals possibly living at intermediate depths, but becoming concentrated as it were on the bottom. The pelagic animals depend for their ultimate source of food, no doubt, largely on the various pelagic plants, the range of which in depth is limited by the penetration of sea-water by the sunlight, and probably to an important extent is dependent on the symbiotic combinations of radiolarians with zooxanthella. But a large part of their food-supply is also constituted by animal and vegetable debris derived from the coasts, either directly from the littoral zone or by rivers and the action of the tides from terrestrial life. Immense quantities of shore-debris have been dredged from deep water near coasts, and deep-sea life appears to diminish in abundance as coasts are receded from. Unfortunately our knowledge of pelagic vegetable life is very imperfect, and it is to be hoped that botanists may be led to take up the subject and bring together what is known with regard to the geological ranges and abundance of the various larger sea-weeds, trichodesmium, diatoms, and other Algæ by which the sea-surface is inhabited. It will, then, be possible to form a nearer estimate of the extent to which these plants are capable of forming a sufficient ultimate food-source for the greater part of the pelagic fauna, and through it of deep-sea life. The question is of importance, because if the deep sea, having no ultimate source of food in itself, derived its main supply from the coasts and land-surfaces in the early history of the habitation of the globe by animals, there can have existed scarcely any deep-sea fauna until the littoral and terrestrial faunas and floras had become well established.

Whether the littoral and terrestrial plants or the pelagic be proved to have the larger share in composing the ultimate food-source of the deep sea, it seems certain that the food as it reaches the deep sea is mostly in the form of dead matter, and I imagine that the long but slender backwardly-directed teeth of many deep-sea fish, resembling those of snakes, are used rather as aids for swallowing whole other fishes which have fallen from above dead, and thus making the best of an occasional opportunity of a meal, than for catching and killing living prey. In a lecture on "Life in the Deep Sea," delivered in 1880,[1] I suggested that putrefaction of organic matter, such as ordinarily occurs elsewhere, may possibly be entirely absent in the deep sea, the Bacteria and other microphytes which cause it being possibly absent. Some interesting experiments with regard to this question have lately been made by M. A. Certes.[2] He added to sterilised solutions of hay-extract, milk, broth, and other organic nutrient fluids mixed with sea-water, with the usual necessary precautions, small quantities of deep-sea mud, or deep-sea water, procured by the *Travailleur* and *Talisman*. In some experiments air was present; others were made *in vacuo*. In nearly all the former putrefaction occurred after some time, especially after application of warmth, and micro-organisms were developed, whilst the latter remained without exception sterile, apparently indicating that the microbes which live where air is absent are not present in the deep sea. The others, which developed in the presence of oxygen, may possibly have sunk from the surface to the bottom, and have retained their vitality, although it is not improbable that they may be incapable of active existence and multiplication under the physical conditions there existing. M. Certes is to make further experiments on this question under conditions of pressure and temperature as nearly resembling those of the deep sea as possible. In the deep sea the ordinary cycle of chemical changes of matter produced by life is incomplete, there being no plants to work up the decomposition-products. These, therefore, in the absence of any rapid change of the deep-sea waters, must accumulate there, and can only be turned to account when they reach the surface-waters on the littoral regions.

Many interesting results may be expected to be obtained when the histology of animals from great depths comes to be worked out, and especially that of the special sense-organs. At present very little has been attempted in this direction, principally, no doubt, because deep-sea specimens are too precious to be used for the purpose. In a remarkable scopelid fish dredged by the *Challenger* from deep water, *Ipnops murrayi* of Dr. Gunther, the eyes are curiously flattened out and occupy the whole upper surface of the mouth. They are devoid of any trace of lens or iris, and, as appears from observations by Mr. John Murray and my own examination of his preparations, the retina consists of a layer of long rods, with a very thin layer indeed of nerve-fibres in front of it, and apparently no intervening granular ganglionic or other layers. The rods are disposed in hexagonal bundles, the free ends of which rest on corresponding well-defined hexagonal areas, into which the choroid is divided. It is probable that aberrant structures may be found in the retinas of deep-sea fish, which may conceivably help towards physiological conclusions as to the functions of the various components. With regard to the all-important question of the nature of the light undoubtedly present in the deep sea, it is hardly possible to accept Prof. Verrill's recent startling suggestion that sunlight penetrates to the greatest depths with perhaps an intensity at from 2000 to 3000 fathoms equal to that of some of our partially moonlight nights. Such a conjecture is entirely at variance with the results of all experiments on the penetration of sea-water by sunlight as yet made by physicists, results which have prevented other naturalists from adopting this solution of the problem.

The progress of research by experts on the deep-sea fauna confirms the conclusions early formed that it is impossible to determine any successive zones of depth in the deep-sea regions characterised by the presence of special groups of animals. Within the deep-sea region the contents of a trawl brought up from the bottom give no evidence which can be relied on as to the depth at which the bottom lies within a range of at least 2500 fathoms. Some groups of animals appear to be characteristic of water of considerable depth, but representatives of them struggle up into much shallower regions. Thus of the remarkable order of Holothurian Elasipoda nearly all the representatives occur at very considerable depths, and their numbers diminish shorewards, but one has been found in only 100 fathoms. Again, the Pourtalesidæ range upwards into about 300 fathoms, and the Phormosomas, which Loven considers as eminently deep-sea forms, range up to a little over 100 fathoms depth, and are nearly represented in shallow water at a depth of only five fathoms by Asthenosoma. As has often been pointed out before, there are numerous genera, and even species, which range even from the shore-region to great depths.

The fact that zones of depth cannot thus be determined adds seriously to the difficulties encountered in the attempt to determine approximately the depths at which geological deposits have been found. Dr. Theodore Fuchs,[1] in an elaborate essay on all questions bearing on the subject, has attempted to determine what geological strata should be considered as of deep-sea formation, but, as he defines the deep-sea fauna as commencing at 100 fathoms and extending downwards to all depths, his results may be considered as merely determining whether certain deposits have been found in as great a depth as 100 fathoms or less, a result of little value as indicating the depths of ancient seas or the extent of upheaval or depression of their bottoms. Mr. John Murray has shown that the depths at which modern deep-sea deposits have been formed can be approximately ascertained by the examination of their microscopical composition and the condition of preservation of the contained pelagic and other shells and spicules.

The most important question with regard to life in the ocean, at present insufficiently answered, is that as to the conditions with regard to life of the intermediate waters between the surface and the bottom. It is most necessary that further investigations should be made in extension of those carried out by Mr. Alexander Agassiz with similar apparatus—a net, or vessel, which can be let down to a certain depth whilst completely closed,

[1] Lecture delivered at the Royal Institution, March 5, 1880, *Nature*, vol. xxi. p. 592.

[2] "Sur la Culture, à l'abri des Germes atmosphériques, des Eaux et des Sédiments rapportés par les Expéditions du *Travailleur* et du *Talisman*, 1882, 1883," *Comptes Rendus*, No. 11, 11 mars 1884, p. 690.

[1] "Welche Ablagerungen haben wir als Tiefseebildungen zu betrachten?" *Neues Jahrbuch für Mineralogie, Geologie, und Paläontologie*, II. Beilage. Bd. 1882.

then opened, lowered for some distance, and again closed before it is drawn to the surface. The greatest uncertainty and difference of opinion exist as to whether the intermediate waters are inhabited at all by animals, and, if they are inhabited, to what extent; and these intermediate waters constitute by far the greatest part of the ocean. If we estimate roughly the depth of the surface-zone inhabited by an abundant pelagic fauna at 100 fathoms, and that of the zone inhabited by the bottom animals at 100 fathoms also, the average depth of the ocean being about 1880 fathoms, it results that the intermediate waters, concerning the conditions of life in which we are at present in the utmost uncertainty, really represent more than eight-ninths of the bulk of the entire ocean. Great care should be exercised in drawing conclusions from the depths ascribed to animals in some of the memoirs in the official work on the *Challenger* Expedition. The scientific staff of the Expedition merely recorded on each bottle containing a specimen the depth from which the net in which the specimen was found had been drawn up. In many instances, from the nature of the specimen, it is impossible that it can have come from anywhere but the bottom, but in many others it is quite possible that a particular specimen may have entered the net at any intermediate depth, or close to the surface, and this is a matter on which the author of the monograph in which the specimen is described can form the best conclusion, if one can be formed at all from his knowledge of the animal itself. In all doubtful cases the mere record of the depth must be received with caution.

Just as before the commencement of the present period of deep-sea research there was a strong tendency amongst naturalists, owing to the influence of the views of Edward Forbes, to refuse to accept the clearest evidences of the existence of starfish and other animal life on the sea-bottom at great depths, so there seems now to have sprung up in certain quarters an opposite tendency, leading to the assignment of animals possibly of surface origin to great depths on inconclusive evidence.

With regard to the constitution of the deep-sea fauna, one of its most remarkable features is the general absence from it of Palæozoic forms, excepting so far as representatives of the Mollusca and Brachiopoda are concerned, and it is remarkable that amongst the deep-sea Mollusca no representatives of the *Nautilidæ* and *Ammonitidæ*, so excessively abundant in ancient periods, occur, and that *Lingula*, the most ancient Brachiopod, should occur in shallow water only.

There are no representatives of the most characteristic of the Palæozoic corals, such as *Zaphrentis*, *Cystiphyllum*, *Stauria*, or *Goniophyllum*. Possible representatives of the *Cyathonanidæ* have indeed been obtained in *Gruyina*, described by Prof. Martin Duncan, and *Haplophyllia* and *Duncania*, described by the late Count Pourtales, but the *Cyathonanidæ* are the least observant and characteristic members of so-called *Rugosa*. Pourtales justly felt doubtful whether the arrangement of the septa in four systems instead of six could in itself be considered as a criterion of the *Rugosa*,[1] and in the cases of *Haplophyllia* and *Duncania* the septa may be described rather as devoid of any definite numerical arrangement than exhibiting any tetrameral grouping. Further, I have lately examined by means of sections the structure of the soft parts of *Duncania* in a specimen kindly given to me by Mr. Alexander Agassiz for the purpose, and find that with regard to the peculiar arrangement of the longitudinal septal muscles and the demarcation of the directive septa the coral agrees essentially with the henactinian *Caryophyllia* and all other modern *Madreporaria* the anatomy of which has been adequately investigated.

There are further no representatives of the ancient *Alcyonarians*, forming massive coralla, the *Helioporidæ* and their allies, in deep water, no *Palæocrinoids*, *Cystidea*, or *Blastoidea*, no *Palechinoidea*, no *Trilobites*, no allies of *Limulus*, no *Ganoids*. Further, other ancestral forms, certainly of great antiquity, although unrecorded geologically, such as *Amphioxus*, do not occur in deep water. It might well have been expected that, had the deep sea been fully colonised in the Palæozoic period, a considerable series of representative forms of that age might have survived there in the absence of most of the active physical agents of modification which characterise the coast regions.

From the results of present deep-sea research, it appears that almost all modern littoral forms are capable of adapting themselves to the conditions of deep-sea life, and there is no reason why Palæozoic forms should not have done so if the abyssal conditions were similar to those now existing, just as a considerable number of forms of the chalk period have survived there. In fact, however, most of the survivals of very ancient forms—*Heliopora*, *Limulus*, *Amphioxus*, *Dipnoi*, *Ganoids*—occur in shallow seas or fresh water.

With regard to the origin of the deep-sea fauna, there can be little doubt that it has been derived almost entirely from the littoral fauna, which also must have preceded, and possibly given rise to, the entire terrestrial fauna. Although the littoral, and even its offspring, the terrestrial faunas, have undoubtedly, during the progress of time, contributed to the pelagic fauna, and although it is very likely that the first traces of life may have come into existence in the shallow waters of the coast, it is not improbable that we should look to the pelagic conditions of existence as those under which most of the earliest types of animal life were developed. Nearly all the present inhabitants of the littoral zone revert to the pelagic free-swimming form of existence in their early developmental stages, or in cases where these stages have been lost can be shown to have once possessed it. And these pelagic larval forms are in many cases so closely alike in essential structure, though springing from parents allied but widely differentiated from one another in the adult form, that it is impossible to regard them as otherwise than ancestral. Had they been produced by independent modification of the early stages of the several adult forms as a means of aiding in the diffusion of the species, they must have become more widely differentiated from one another. The various early pelagic free-swimming forms, represented now mostly only by larvæ, gradually adapted themselves to coast life, and underwent various modifications to enable them to withstand the beating of the surf on the shores and the actual modifying alterations of the tides, which, together with other circumstances of coast life, acted as strong impulses to their further development and differentiation. Some developed hard shells and skeletons as protections; others secured their position by boring in the rocks or mud; others assumed an attached condition, and thus resisted the wash of the waves. A remarkable instance in point, about the circumstances of which there can be little doubt, is that of the *Cirripedia*. The *Cypris* larva of *Balanus*, evidently of pelagic origin, sprung from a *Nauplius*, fixes itself by its head to the rocks and develops a hard conical shell, by means of which it withstands the surf in places where nothing else can live. In the same way the *Planula* larva, the Palæozoic cœlenterate form, produces the reef coral and various other forms specially modified for and by the conditions of littoral existence. Similarly echinoderms, Mollusca, Polyzoa, Crustacea, recapitulate in their ontogeny their passage from a pelagic into a littoral form of existence.

It is because the ancestors of nearly all animals have passed through a littoral phase of existence, preceded mostly by a pelagic phase, that the investigations now being carried on on the coasts in marine laboratories throw floods of light on all the fundamental problems of zoology. From the littoral fauna a gradual migration must have taken place into the deep sea, but probably this did not occur till the littoral fauna was very fully established and considerable pressure was brought to bear on it by the struggle for existence. Further, since a large share of the present food of deep-sea animals is derived from coast-debris, life must have become abundant in the littoral zone before there could have been a sufficient food-supply in the deeper regions adjoining it. Not until the development of terrestrial vegetation and animal life can the supply have reached its present abundance. Such a condition was, however, certainly reached in the Carboniferous period. From what has been stated as to the general absence of representatives of Palæozoic forms from the deep sea, it is just possible that if deep oceans existed in Palæozoic periods they may not have been colonised at all, or to a very small extent, then, and that active migration into deep waters commenced in the secondary period. Very possibly the discharges of carbonic acid from the interior of the earth, which Prof. Dittmar believes may have been sufficient to account for the vast existing deposits of coal and limestone, may have been much more abundant than at present over the deep-sea beds in the Palæozoic period, and have rendered the deep waters more or less uninhabitable.

In his splendid monograph on the *Pourtalesia*,[1] which has recently appeared, Prof. Loven has dwelt on the peculiar importance of the littoral region, and of the infinity of agencies present in it "competent to call into play the tendencies to vary

[1] "Zoological Results of the Hassler Expedition." See *Cat. Mus. Comp. Zool. Harvard*, No. viii. 1874, p. 44.

[1] *On Pourtalesia, a Group of Echinoidea*, by Sven Loven. (Stockholm. 1883.)

which are embodied in each species." He treats of the origin of the deep-sea fauna from that of the littoral region. It is impossible here to follow him in his most valuable speculations. In one matter, however, I would venture to express a difference of opinion. He regards the littoral forms of invertebrates as migrating into the deep sea by the following process: Their free-swimming larvæ are supposed to be carried out by currents far from land, and then, having completed their development, to sink to the bottom, where a very few survive and thrive. It is hardly to be conceived that any animal, especially in a young and tender condition, could suddenly adapt itself to the vast change of conditions entailed in a move from littoral to deep-sea life. It seems to me much more likely that the move of animals from the shallow to the deep sea has been of the most gradual kind, and spread over long series of generations, which may have migrated downwards, perhaps a fathom or so in a century, partly by very slight migrations of the adults, partly by very short excursions of larvæ. Thus alone, by almost insensible steps, could animals, such as those under consideration, be enabled to survive an entire change of food, light, temperature, and surroundings.

NOTES

WE have received a box of plants from the Ben Nevis Observatory, including specimens of *Saxifraga stellaris*, from a height of 4400 feet, and *Armeria vulgaris*, from 4370 feet. The plants of these two species, with the numerous flowers which covered them, are as large and well grown as any we have ever seen at lower levels. There is also a specimen of *Gnaphalium supinum*, fairly well grown and in flower, from a height of 4370 feet, and a single plant of *Oxyria reniformis* from 4390 feet, also fairly well grown, but not in flower. The interest attached to the collection is the great height at which they have been found growing in full vigour, the heights being greater than those hitherto given in our "Floras" as the limits of growth of the species in the British Islands. In the case of *Armeria vulgaris* the height is considerably greater, 3800 feet being the limit assigned to this species in Hooker's "British Flora."

THE Hygienic Congress has voted a resolution requesting the Dutch Government to convoke an International Conference on Cholera, for the purpose of establishing a permanent International Epidemical Committee, and preparing an international penal sanitary code. The Congress has denounced the modern system of education and competitive examinations as injurious to health.

ON the afternoon of Tuesday, August 12, the foundation-stone of the new Meteorological Observatory at Falmouth was laid by the Right Hon. the Earl of Mount Edgcumbe, the President of the Royal Cornwall Polytechnic Society, in the presence of an assembly of over 400 persons. Some eighteen months ago the Meteorological Council of London gave notice that they intended to maintain only three first-class Observatories in the British Isles, and that the grants to four out of the seven then existing would cease on December 31, 1883. The three which they decided on continuing to subsidise were Kew, Valentia, and Aberdeen, but in view of the good work done and the value of the observations, the Council expressed the hope that local efforts would succeed in maintaining the Observatories at the other four stations. The Meteorological Committee of the Royal Cornwall Polytechnic Society, which has the local management of the Observatory, made strenuous efforts to retain the institution in Falmouth, and, after much negotiation, the Meteorological Office agreed to continue their grant of 250*l.* a year, provided a new building were erected on a site approved by them, at some distance from the harbour, so as to be free from the disturbing influences on the wind which the harbour and its surroundings were supposed to cause. The Polytechnic Society took the matter up with great zeal and determination, and the result has been that matters in connection with the new Observatory have become sufficiently matured to admit of the foundation-stone being laid. The new Observatory is situate at the top of Killigrew Street, opposite Belmont. It will not take the shape of the present one, with its high octagonal tower, but will be built in the form of a villa residence, one portion to be the dwelling-house of the superintendent (Mr. E. Kitto, F.R.Met.S.), the other to be specially constructed for the reception of the various instruments. The apparatus in the present Observatory will be transferred to the new one, and the observations now carried on will be continued without alteration, so that the Falmouth Observatory will still be one of the first-class Observatories of the United Kingdom, under the control of the Meteorological Office. The instruments are a barograph, for recording the changes of the barometer; a thermograph, for recording the variations of both the dry and the wet bulb thermometers; the anemograph, to measure the force and direction of the wind; a sunshine recorder; and a self-registering rain-gauge. In addition to these, the Royal Society have made a grant for the purchase of a complete set of magnetographs for recording the declination of the needle, and the force of the magnetic currents. Although these will entail an extra annual expense of 50*l.* a year, the Polytechnic Society has boldly undertaken the responsibility of this work. Seeing that the great value of magnetic observations depends to a large extent on their being taken simultaneously and continuously at stations far removed from one another, and that there is now no first-class magnetic Observatory in the British Isles west of Oxford, Falmouth Observatory may be expected to supply a valuable additional data to our knowledge of this comparatively little-known subject. The Observatory will be under the superintendence of Mr. E. Kitto, the Secretary of the Royal Cornwall Polytechnic Society.

PROF. C. V. RILEY, U.S. Entomologist, and Curator of Insects in the U.S. National Museum, left for home on the 23rd, expecting to arrive in time for the meeting of the American Association for the Advancement of Science in Philadelphia. During his two month's sojourn in Europe he has twice been on the Continent, and has visited correspondents and acquaintances both there and in England, examining the insect collections in various museums, and especially in our own at South Kensington. He speaks favourably of the lasting influence for good which the International Forestry Exhibition at Edinburgh will have, and of the Serrel serigraph—an American invention which has of late years been perfected in Lyons, and which he thinks is destined to revolutionise silk-reeling and profoundly influence silk-culture, which is just now attracting unusual attention in the States. He was also much interested with the investigations into the life-habits of the *Aphididæ* that are being carried on by Jules Lichtenstein at Montpellier, and with the thoroughness with which the French authorities encourage experimental research in advanced agriculture. He received a warm welcome at Montpellier, whither he went at the invitation of the French Minister of Agriculture to explain some new methods of dealing with the Phylloxera, and where he found his own recommendations of previous years so fully carried out. He was also surprised at the very extensive and successful experiments with American vines carried on at Pageset near Nîmes. At a meeting of the Société d'Agriculture d'Hérault, held on June 30, he read a paper entitled "Quelques Mots sur les Insecticides aux États-Unis, et proposition d'un nouveau remède," which appears in full, with an account of the discussion, &c., in *Le Messager Agricole* for July 10, 1884. The "new" remedy is kerosene emulsion, which has been successfully used, especially against *Coccidæ*, in the States. Its application against the Phylloxera is recommended in much the same manner as is used with regard to bisulphate of carbon; the proportions recommended are 300 or 400 grammes of the emulsion in 40 litres of water.

THE Russian Ministry of Marine has distributed among several learned societies a plan for despatching a Russian expedition to the North Pole, starting from North-Eastern Siberia or Jeannette Island, discovered by the *Jeannette* Expedition, and proceeding entirely on foot over the ice in several parties, with large depots in the rear. It is thought that there are many islands north of Jeannette Island which may be explored.

THE following lecture demonstrations will be given in the Hygienic Laboratory at the International Health Exhibition during the forthcoming week by Mr. Charles E. Cassal, F.C.S., Chief Demonstrator:—Tuesday, September 2, Arsenic in Wall Papers and Articles of Clothing; Wednesday, September 3, Drinking-Water; Friday, September 5, Common Food Adulterations. The lectures will commence at 4 p.m.

WHILE at Newcastle last week, the Prince of Wales opened a new Library and Museum of Natural History.

HAVING been asked by M. Wilkens if there are not among the plants of Central Asia remains of the Tertiary period corresponding to those which have been discovered among the animals, Dr. A. Regel, in a letter from Tashkend, which has just appeared in the *Bulletin de la Société des Naturalistes de Moscou*, answers that to say anything about the subject would require a closer comparison with fossil plants. This he could not possibly make during his journey. Still, he points out how many plants in the lowlands and in the wild spurs of the highlands have quite special characters: it is sufficient to mention the plants with leather-like leaves, the Salsolaceæ without leaves, which recall the vegetation of Australia and Africa, or the Ericaceæ-like Reaumuriaceæ of Jungaria. He considers, however, such observations "rather æsthetical," and not sufficiently conclusive; he likes better to collect the necessary material for ulterior work.

PROF. RAOUL PICTET, of the University of Geneva, communicates to a local journal a short memoir of his friend, Baron Thenard, who died at his Château of Talmay on August 8. The late Baron was the son of the illustrious chemist of the same name, and, like him, he devoted his life and his fortune to the service of science. The late M. Thenard was especially distinguished for his investigations in agricultural chemistry—investigations which obtained for him in 1865 admission to the French Institute. An extensive landowner in the Departments of the Côte d'Or and Saône-et-Loire, he paid great attention to the perfection of agricultural machinery and implements, to improved methods of husbandry, the discovery of more efficient fertilisers, and the introduction of new fruits and vegetables. In his laboratories at Paris and at Talmay Baron Thenard devoted himself with rare energy to the elaboration of new methods of organic analysis. Some of the substances he desired to examine he placed in closed circuits, full of pure oxygen, in order to measure how much of the gas was absorbed during the process of combustion, the circulation of the gas being actuated by mercury pumps of the Baron's own invention, which Prof. Pictet describes as singularly ingenious pieces of mechanism.

IT is proposed to form, at the Academy of Sciences of St. Petersburg, a special Committee for the concentration of all observations on meteorology, magnetism, rainfall, and thunderstorms, which are now made in Russia, partly under the direction of the Central Physical Observatory, and, to a great extent, by the initiative of the Geographical Society, the Departments of Ways and Communications, Agriculture, and so on, or privately. The Committee will consist of members of the Academy of Sciences, the Geographical Society, and those Ministries which grant sums of money for meteorological observations.

THE last number of the *Isvestia* of the East Siberian branch of the Geographical Society (vol. xiv. fasc. 4 and 5) contains some interesting notes on the paths that connect Verkhoyansk with Yakutsk, with two maps of the country, by M. Gorokhoff; a note on the Ike-Aral settlement in Transbaikalia, by M. Mikhailoff; and letters from the Polar meteorological station at Sagastyr. The last of these is dated November 25, 1883, and we notice with pleasure that the zeal of the scientific staff of the station continues unabated; the news that they have been allowed to stay for a second winter at the station has been received by them with great pleasure; and Dr. Bunge, already on his journey home, returned immediately from Bulun as soon as he met with the Cossack who brought a letter from the Geographical Society granting the necessary money for a second year's stay at the mouth of the Lena.

IT has been resolved, it seems, to drain the beautiful Merjelen Lake, seen by all tourists who climb the Eggishorn and visit the great Aletsch glacier. From time to time it breaks its icy barriers, leaps in a mad torrent into the bed of the Marsa and spreads terror and destruction in all the valley of the Upper Rhone. The Merjelen contains 10,000,000 cubic metres of water, is 50 m. deep at the point where it is bounded by the Aletsch glacier, and 12·50 m. at the opposite extremity. The basin of the lake is 1500 m. long, its direction is from west to east, and at the eastern end is the overflow. It is here that the proposed operation will be effected. The opening, 540 m. long and 12·50 m. deep, will thus be at the back of the lake, and its effect will be to lower its level by 12·50 m., and diminish its volume by about one-half, the present mean depth being some 25 m., and although, so say the engineers, the operation may not absolutely prevent future floods, they will be rendered thereby both much rarer and far less dangerous.

La Lumière Électrique has sent a scientific mission of six of its staff in order to report on the Exhibition of Philadelphia and the state of electrical industries in America.

AN Imperial decree, issued this month, interdicts the delivery from Russian circulating libraries to their subscribers of the scientific works of the following authors:—Agassiz, Büchner, Huxley, Lubbock, Lewes, Moleschott, Reclus, Adam Smith, Spencer, Vogt, and Zimmermann. The works of Charles Darwin have already been submitted to the same interdiction.

THE principal article in the current number of *Petermann's Mittheilungen* is on the Trans-Caspian and the neighbouring regions, based on the travels of Lessar. It deals with Atek, the roads from Saraks and Merv to Herat, including four days in Afghanistan, Meshed, the road from Saraks to Merv, with an account of the latter town, and Merv to Bokhara. The paper is accompanied by a map of Merv and the Russo-Persian frontier. Another paper, of present importance (also with a map) is one on the territory of the International Association on the Congo.

A CORRESPONDENT of the *Times* from Pekin, writing on mining in China, refers to the various obstacles which have stood in the way of progress in this direction in the Middle Kingdom. First there is the mysterious but powerful *fêng-shui*, or geomantic influences, an all-pervading superstition, but occasionally elastic, and yielding to expediency, as the spread of telegraphs in the country during the past two years has demonstrated. Then comes the innate suspicion and dislike of foreigners, by whom the mineral wealth of China has been explored, and the importance of working it demonstrated. But "the most efficient obstacle of all" is the ignorance of the officials of the application of science to industry. The long and absorbing devotion to Chinese literature which is necessary to obtain official employment renders any other study, even did the taste or the means of pursuing it exist, all but impossible. The rulers of China fear to avail themselves largely of the services of the "base mechanical" foreigner, unless as a humble instrument, which they cannot always be sure that

he will consent to remain. Nevertheless marked advance has been made in certain directions. Apart from the employment of all the modern military and naval inventions, native-armed steamships have become common enough; the telegraphs are rapidly extending all over the country, and only last week a telegraph office was opened at Pekin itself. Railways are to be introduced gradually, and the correspondent narrates the story of an attempt to work coal-mines on Western methods. The Kaiping mines, which are specially referred to, have not been altogether a financial success, on account of the difficulties of transport, the necessity of constructing a rough canal for part of the way, and the refusal of the authorities to permit of the regular employment of steam locomotives between the mines and the nearest waterway. Still the experiment is stated to be full of hope, for the causes which have rendered it a loss to its promoters can be remedied, it is said, by a stroke of the pen.

A RECENT number of the *China Review* contains an article on the Chinese and Japanese plants found in Normandy. During a recent holiday in Europe the writer, M. Fauvel, was struck by the quantity of exotic and even sub-tropical plants cultivated there, and amused himself by searching for the Chinese and Japanese species. The district examined was chiefly that round Cherbourg. The paper describes first the trees and shrubs, which are in a majority, and then refers to the herbaceous flowers and plants, ornamental and useful. Among these were the *Camellia japonica*, the *Chamærops excelsa*, or Chinese palm, the deciduous magnolias of China, *Paulownia imperialis*, wistaria, the rhododendrons and azaleas of China and Japan, the Japanese quince (*Cydonia japonica*), and many others, all of which will be found noted in a paper which may be read with interest by many who take but a limited interest in botany.

DR. CHARLES CLAY contributes to the *Chemical News* of August 8 an interesting reminiscence of Dalton. Dr. Clay was a pupil of Dalton's, and he tells very graphically his adventures in search of four bottles of fire-damp, for which he had to proceed from Manchester to Oldham.

A GROTTO, from 8 to 10 metres high, has been discovered in a rock, washed by the sea, in the Morbihan, by M. Gaillard. He has since continued his researches, at low water, and found some human bones, ancient earthenware marked with allegorical figures, and coins believed to have been struck by the early Gauls.

THE National Electrical Commission, *Science* states, met in Philadelphia on August 7. It was decided that the Conference to be conducted by the Commission will be called for Monday, September 8, to be then continued from day to day, as may be found necessary. The invitations to the Conference will be confined to physicists of eminence, and to experts in the practical management of electrical appliances and apparatus. It is proposed to extend special invitations to prominent foreign visiting electricians. It was also decided to issue a circular inviting the conferees to submit a paper to be read before the Conference. It is not definitely known what subjects will be discussed at the Conference, but the following matters have been suggested: the sources of electrical energy; the theoretical conditions necessary to the most efficient construction of the dynamo-electric machine for the various purposes of practical work; the electrical transmission of energy; the systems of arc and incandescent lighting; the theory of the electric arc, storage batteries, electro-metallurgy; lighthouses for the coast; applications of electricity to military and mining engineering; lightning protection; induction in telephone lines, and the problem of long-distance telephoning; the question of underground wires; atmospheric electricity; earth-currents and terrestrial magnetism; photometry and standards for photometric measurements; the ratio of the electro-magnetic to the electro-static system of units, and the electro-magnetic theory of light; and finally, on account of the pressing necessity for accurate and uniform electrical measurements, it is probable that the question of establishing a National Bureau of Physical Standards will receive proper attention.

THE additions to the Zoological Society's Gardens during the past week include a Gelada Baboon (*Theropithecus gelada* ♀) from the Province of Amara, Abyssinia, presented by H. E. Lidge, Mercha Workee, Abyssinian Envoy; a Red-crested Cardinal (*Paroaria cucullata*) from South America, presented by Mr. John W. Miers; an African Elephant (*Elephas africanus* ♂) from Abyssinia, deposited by Her Majesty the Queen; two Cape Hunting Dogs (*Lycaon pictus*) from South Africa, two Picui Doves (*Columbula picui*) from South America, deposited; a Common Cormorant (*Phalacrocorax carbo*), British, received in exchange.

OUR ASTRONOMICAL COLUMN

COMET 1884 *b* (BARNARD, JULY 16).—Herr Stechert of Kiel has ascertained that the apparent deviation of the orbit of this comet from a parabola, mentioned last week, is due to error in the telegraphed position on the night of discovery, and that observations between July 23 and August 10, at Algiers and Rome, are well represented by the following parabolic elements:—

Perihelion passage, 1884 August 18·18264 G.M.T.

Longitude of perihelion	303° 31′ 27″	M.Eq. 1884·0
„ ascending node ...	357 40 19	
Inclination	6 52 12	
Log. perihelion distance	0·140670	

Motion—direct.

Small inclination and direct motion have long been considered to favour periodicity, though we now have some striking exceptions. In the above orbit the comet, in approaching the sun, passes very near to the orbit of the planet Jupiter; thus, at a true anomaly of 240° 30′, corresponding to heliocentric longitude 184°, the distance of the two orbits is less than 0·2 of the earth's mean distance from the sun, and the comet is, at this point of its track, 454 days before perihelion passage, or on the last occasion in May 1883, when the planet was far distant.

The following positions for midnight at Berlin have been calculated by Herr Stechert:—

	R.A. h. m	N.P.D. ° ′	Log. distance from Earth
Sept. 15	19 21·4	119 23	9·8470
16	— 25·4	119 3	
17	— 29·3	118 43	9·8548
18	— 33·2	118 22	
19	— 37·1	118 1	9·8629
20	— 40·9	117 40	
21	— 44·7	117 19	9·8713
22	— 48·5	116 57	
23	19 52·2	116 35	9·8801

The above elements also give these positions:—

12h G.M.T.	R.A. h. m.	N.P.D. ° ′	Distance from Earth.	Distance from Sun.
Oct. 20	21 18·7	105 55	1·041	1·656
Nov. 19	22 29·9	97 55	1·504	1·912

The intensity of light on October 20 is 0·34, that on November 19, 0·12, its value at discovery on July 16 being 1·16.

M. Perrotin has made the following observation:—

M.T. Nice h. m. s.	R.A. h. m. s.	N.P.D. ° ′ ″
August 15, 8 48 54	17 13 6·79	126 28 28·4

He remarks: "La comète a l'aspect d'une nebulosité assez mal définée de 1′ 30″ de diamètre environ, présentant des granulations brillantes vers le centre."

KEPLER'S NOVA OF 1604.—Those who have taken interest in the actual configuration of stars near the place of the famous *Stella nova in pede Serpentarii* will be aware that Chacornac has a star of the tenth magnitude (or perhaps of the ninth, the symbol being a little ambiguous) in a position near that of the

star of 1604, where none has been since observed. It was of course desirable to clear up this difficulty, and Mr. Herbert Sadler appears to have done so effectually. He has remarked that in the part of the Chart No. 52, where the place of Kepler's star falls, the positions of a number of the brighter stars are incorrectly laid down for the professed epoch of the Chart, 1855 January 1, their right ascensions being uniformly in defect of the true ones; and he notes that, when the assigned place of Chacornac's star is corrected in right ascension to about the amount that several known stars in the vicinity require, it falls into the place of No. 16872 of Oeltzen's Argelander, so that, in Mr. Sadler's view, the stars are identical, and there can be no reasonable doubt that he is correct. It is very satisfactory to have eliminated the difficulty with regard to Chacornac's star, particularly as the place of Kepler's star can hardly be said to be comparable in accuracy with that of Tycho's star of 1572.

The following are places of three of Argelander's stars for 1855·0, on comparing which with the positions assigned on Chacornac's Chart No. 52, its distortion will be evident:—

		h. m. s.		° ′ ″
Oeltzen 16848 ...	R.A.	17 21 19·6 ...	N.P.D.	112 49 47
,, 16816 ...	,,	17 19 37·4 ...	,,	110 50 13

The Yale College Observatory, U.S.—The fine heliometer of this Observatory is now in active charge of Dr. W. L. Elkin, who had given special study to the theory of this instrument at Strasburg, and subsequently had two years' valuable experience in the use of it, in conjunction with Dr. Gill, H.M. Astronomer at the Cape of Good Hope. From the Report to the Board of Managers in June last, it appears that the expenses attending the use of the heliometer have been guaranteed for a period of three years by ten subscribers; and Dr. Elkin, who took charge of it on January 15, is already able to report upon work accomplished, though time is necessarily occupied in the general investigations of the instrument, as scale determinations, &c. A triangulation of the Pleiades has been commenced, with the view to comparison with Bessel's measures of this group, made with the Königsberg heliometer nearly half a century ago, as well as with the later observations of M. Wolf at the Observatory of Paris; about one-third of the proposed measures had been completed before the stars were lost in the sun's rays in the spring, and it is hoped to complete the work during the last four months of the present year. A considerable amount of time has been devoted to determination of places of the moon relative to stars within measuring-distance of the heliometer, with the view to determining the parallactic inequality in the moon's motion, the deduction of which from meridian and other observations is, as Dr. Elkin remarks, attended with some difficulty. Measures of the diameter of Venus near her inferior conjunction have also been secured. There cannot be a doubt that, in Dr. Elkin's hands, most valuable results will accrue from the regular employment of the powerful measuring-instrument of Yale College Observatory. On the Board of Managers of the Institution we remark the well-known names of Profs. Elias Loomis and H. A. Newton.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, August 18.—M. Rolland, President, in the chair.—Obituary discourses pronounced at the obsequies of M. Paul Thenard, by MM. Bouley and Fremy.—Observations of the small planets made with the great meridian instrument of the Paris Observatory during the second quarter of the present year, by M. Mouchez.—Essays in stellar photography, with a view to the construction of maps of the heavenly bodies, by MM. Paul and Prosper Henry, by M. Mouchez. The results so far obtained have been secured by means of an objective with a diameter of 0·16 m. and 2·10 m. focal distance. They represent on a surface of rather less than a square decimetre a section of the Milky Way of 3° of right ascension, and 2° declination, showing 1500 stars from the sixth to the twelfth magnitude. The images of these stars have a diameter nearly proportioned to their brilliancy, except the yellow stars, which appear somewhat fainter. These encouraging results have induced MM. Henry, who are skilful opticians as well as experienced observers, to undertake the construction of a much larger objective with a diameter of 0·34 m., specially adapted for photographing the celestial orbs.—Note on a new method of representing graphically the speed of railway trains, by M. Léon Lalanne.—Rep on various communications relating to the cholera, by the Co missioners, MM. Vulpian, Marey, Richet, Bert, Pasteur, Boul and Gosselin. Thirty fresh communications received by the A demy during the month of August have been examined with prac cally no results. Even Dr. Peyrusson's views regarding the effica of borax and boric acid are purely theoretic, unsupported by an practical tests.—Account of a new balloon capable of bein guided in any direction and kept under control, by MM. Ch Renard and A. Krebs. The authors claim to have solved th problem of aërial navigation by means of a new balloon of elo gated form, and provided with a screw and helm, which wa successfully tried at Chalais on August 9. After a trip of near five miles, it returned to the starting point, obeying the helm, an executing a series of manœuvres with a precision comparable t that of a screw steamship in the water. Chief dimensions length 50·42 m., diameter 8·40 m., volume 1864 m., total weigh 2000 kilos.—Observations of the Barnard comet made at th Observatory of Nice, by M. Perrotin.—Observations on the sola spots and volcanic eruptions during the year 1883, by M. P Tacchini.—Note on a fixed astronomical telescope, by M. G Hermite.—Note on the freezing-point of saline solutions, by M F. M. Raoult.—On the combinations of telluric acid with th salts of the bioxide of tellurium, by M. D. Klein.—Researche on the modifications produced in the nutrition of the nervou system by mania, lypemania, and epilepsy, by M. A. Mairet.—Researches on the microbe of typhoid fever in man; its cultiva tion, and inoculation of the virus in rabbits, guinea-pigs, poultry pigeons, pigs, and other animals, by M. Tayon.—Note on th slow period of latent excitation in the muscles of invertebrat animals, by M. H. de Varigny.—Account of a new variety o Rhizopod found on the Arcachon coast, south of Bordeaux, by M. J. Kunstler.—Note on a relation between the temperature of fusion of simple bodies and their atomic weights, by M. Chapel The same author presented a paper on the coincidence of seismi and meteorological phenomena with the return of the Augus meteoric showers.

FUNGI AND BACTERIA

Vergleichende Morphologie und Biologie der Pilze, Mycetozoen, und Bacterien. By A. De Bary. (Leipzig: Engelmann, 1884.)

THOSE of us who have been awaiting the publication of a new edition of De Bary's "Morphologie und Physiologie der Pilze, Flechten, und Myxomyceten" of eighteen years ago, will be neither surprised nor disappointed to find that the author has felt compelled to change the title as well as to effect such important alterations in the text that the book is not only virtually but really a new one. This is, moreover, extremely satisfactory, since it shows that the province of mycology has been extended during the period named. How far this extension is due to the labours and influence of the writer of the book before us is well known to all botanists.

In some respects the general plan of the old book has been followed, and many of the woodcuts have been retained; but the large and at that time important section on the reproductive organs in the previous edition is no longer to be found as a separate part of the present book, the results of more recent investigations having completely altered the position of the question as to the sexual reproduction of the Fungi. This fact is of course also a motive in the very different views on classification held by the author now, as contrasted with those published in the earlier book. These and the addition of the Bacteria as an entirely independent group of organisms, are among the principal points of difference in the general plan of the book. That they are by no means the only changes in plan, however, is to be seen at a glance on comparing the two editions.

The present work is divided into three "Parts," devoted to the Fungi, the Mycetozoa (Myxomycetes), and the Bacteria respectively. Under the Fungi proper, there are three chapters devoted to "General Morphology," including Histology, the Segmentation of the Thallus, and the Morphology of the Spore; the latter being very fully treated of, and many new facts being added. The second part deals with the groups of Fungi themselves, and their evolution; the theoretical portions of Chapter IV. being extremely comprehensive and clear, and touching upon matters of the widest biological interest. Chapter V. deals with the various groups comparatively and in detail. Starting with the Peronosporeæ, the author follows the series through the main Ascomycetous series to the Uredineæ, in conformity with his now well-known views on the classification, dealing by the way with those groups which diverge from the main series or are still doubtfully situated.

The third part of the main subject (Chapters VI. and VII.) is devoted to the physiology of the Fungi, including the phenomena of parasitism and the commensalism of the Lichens, and bringing us through by far the larger part of the book.

The *Mycetozoa* (Chapters VIII. and IX.) occupy nearly 40 pages of most interesting matter, including a discussion as to the position of these remarkable organisms, and an account of what is known as to their physiology.

The *Bacteria* or Schizomycetes are dealt with separately and in detail at the conclusion of the book. Chapter X. is devoted to their morphology, and discussions as to their position in the system, and the meaning of "species." A sharp comparison of the extreme views on this subject is dealt with shortly, and in the author's characteristic style. Probably the most fascinating chapter in the book (unless Chapter IV. be excepted) is the last one, dealing with the physiology and life-history of the Bacteria, and of course touching the subjects of pathology and adaptation to different media and conditions with a master hand; and it will be an enormous boon, and should be a stimulus, to have the facts as to the resistance of germs, conditions of development, &c., of these important organisms sifted by an author of such wide experience.

Enough has been said to show that the present book is rather to be considered as a new work than as a second edition of the "Morphologie und Physiologie der Pilze, &c." But it is not only in that so much new matter has been added and a different arrangement been found necessary that this book differs from the former one; the theoretical portions have also undergone changes even more striking and important than the statements of fact. To put the subject in the shortest possible form:—While the then recent discoveries of Pleomorphism and the reproductive organs by Tulasne and De Bary were leading mycologists to suspect that a reproductive process exists in the case of all the higher Fungi, the prominent doctrine, so to speak, in the older work was in accordance with the expectations which had been aroused. Nevertheless, no better monument to the sagacity of the author could perhaps be suggested than his careful statement of the case of the sexuality of the Ascomycetes, even in 1866.

It is well known now that the investigations of the last eighteen years have gone to show that not only do the reproductive organs gradually become simpler and finally disappear in the higher Fungi, *but that the physiological* processes intrusted to them fade away even earlier—the former depending on the latter, in fact. This doctrine of Apogamy, established by De Bary, of course profoundly affects the work before us. The whole subject of Pleomorphy is also now in a far better position, and we strongly recommend all young botanists to read and mark well the introduction (Chapter IV.) to the second section of this book, which contains much just and trenchant criticism on all these matters, and on past mistakes and future dangers connected with them. The notes on terminology should also be well pondered by the more reckless.

It would take too long to enter further into details as to the classification adopted. It may suffice to point out that the *Peronosporeæ* (and *Ancylisteæ* and *Monoblepharis*), *Saprolegnia*, *Zygomycetes*, and *Entomophthoreæ* are treated as four groups, which, on account of their relations to the Algæ, may be comprehended as the *Phycomycetes*. The main line of the *Phycomycetes* leads us to the *Ascomycetes*, and, further, to the *Uredineæ*. The treatment of the enormous mass of *Ascomycetes* is masterly in the extreme, and testifies better than anything else to the progress made in the biology of these Fungi during the last twenty years. The groups mentioned are regarded as the "Ascomycetous series."

As diverging groups, or such the position of which is

still doubtful, De Bary classifies the *Chytrideæ*, and *Protomyces*, and *Ustilagineæ*, all considered as allied phylogenetically with the *Phycomycetes*: and a series of doubtful *Ascomycetes* (*e.g.* Eidam's *Helicosporangium*; also *Exoascus*, *Saccharomycetes*, &c.), obviously to be placed next the *Ascomycetes* proper. Finally, the huge group of the *Basidiomycetes*, which De Bary regards as connected with the *Uredineæ*, though it is not an easy matter to satisfy one's self of the alliance.

The rigour with which the literature has been sifted is shown in the references given at the end of each section. There is no doubt that Prof. De Bary may be congratulated on once more having written a work which will be a monument to his skill and industry, and a boon to all biologists.

OUR BOOK SHELF

A Monographic Revision and Synopsis of the Trichoptera of the European Fauna. First Additional Supplement (with Seven Plates). By Robert McLachlan, F.R.S., F.L.S., &c. (London: Van Voorst, 1884.)

FOUR years ago, in the preface to his very important and elaborate "Monograph of European Trichoptera," Mr. McLachlan promised to continue from time to time the supplemental notices of which the necessity of the case had already caused two to be appended to the original work. The first of these has just (June) been published; it adds nearly fifty species to those described in the Monograph and its Supplements. Some new forms are noticed to which it has seemed right to assign the rank of varieties, and there is a great deal of additional information as to localities. While all the species in the original work have been passed under review, in one or two instances those belonging to some genera have been thoroughly revised. Very few new genera are indicated, and the author thinks the time has not yet arrived for a complete subdivision of some of the larger generic groups as now constituted. All but six of the additional species are from within the limits of Europe proper, proving how hazardous it would be to conjecture as yet as to the number forming part of the European fauna. While ready and liberal help has been afforded towards the work of this Supplement by many of the author's friends and correspondents, yet it is by one above all the others that the material for it has been accumulated; for to the labours of the Rev. A. E. Eaton in Italy, Portugal, Madeira, the Canary Islands, and elsewhere, the author stands indebted for more than three-fifths of the new species, and though Mr. Eaton is well known as an acute, indefatigable, and successful entomologist, does the remark press less home that "if a foreigner making short holiday tours through certain districts previously unexplored (so far as the Trichoptera are concerned) can produce such results, it is needless to call attention to what *might be done* by residents in the districts"?

Among the genera which have been revised we note Sericostoma, which it is now proposed to divide into two groups, *i.e.* (A) with the Maxillary palpi in the male very prominent and scarcely hairy; and (B) with the Maxillary palpi in the male slightly prominent and very hairy.

Additional and valuable information is given concerning the singular forms belonging to the genus Helicopsyche. The author now acknowledges three European species, while he seems to think that the number will yet be greatly increased. The three species at present stand as *H. sperata*, *H. lusitanica*, and *H. revelieri*. The last species equals *H. shuttleworthii*, and was bred in large numbers by M. Revelière, who found the larvæ in very great abundance in a stream near Porto Vecchio, Corsica. The imago is to be found all the year round, but it seems to require a certain degree of warmth for its emergence, which is always effected in the daytime. The larvæ and pupæ can exist in a very scanty supply of moisture; indeed some specimens which were left untended for many days were found quite active though all the water had evaporated from them, and the sand in which they were was only moist. The building material of the helix-like cases is fine sand-grains; each case forms fully two and a half whorls; the cement-like substance used to bind the sand-grains together is often applied so thickly that the individual grains are inconspicuous.

In the genus Setodes, Mr. McLachlan has discovered a character in the posterior wings which (with others) enables the species of the genus as it now stands to arrange themselves into two sharply defined groups (which will be hereafter considered genera). This character is the presence or absence in the posterior wings of a fold above the apical fork known as No. 5. *S. punctata* and its allies belong to the group in which the fold is absent, while *S. tineiformis*, Curt., &c., belong to the group with the fold.

This "First Additional Supplement" is illustrated by seven plates engraved from the author's drawings in a very creditable manner by Mr. G. Jarman. As the necessities of the case arise, we are promised a "Second Additional Supplement," which will be as gladly welcomed by those taking an interest in this group of insects as the present one is sure to be.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Lœwy's New Telescope System

IN the June number of the *Bulletin Astronomique* there is an important article by M. Lœwy entitled "Description d'un nouveau Système de Télescope," on which, with your permission, I would offer some remarks.

M. Lœwy gives the two possible dispositions or arrangements that allow the principle of the *équatorial coudé* to be applied to the reflecting telescope. He assumes certain optical and mechanical conditions, and on these treats the question exhaustively, giving tables showing the different sizes of the mirrors required and other data obtained by the use of formulæ based on those conditions.

The practical difficulties are also dealt with and suggestions made for forms of mountings. There is also a suggestion of the MM. Henry to close the mirrors from the open air by means of a parallel plate of glass to protect them from the effects of dust, moisture, &c.

This subject has a particular interest for me (as I have no doubt it has also for many others), and I have considered for some time the mechanical difficulties from a different point of view from that of M. Lœwy, coming thereby to conclusions differing considerably from those given by him. There is, of course, much to be said on such a subject as this, involving as it does so many points that can be dealt with in so many different ways, and some of these I should much like to say more on by and by; but at this holiday time of year I will only offer the following observations:—

1. It is of the first importance to reduce as much as possible the distance (δ) between the middle mirror of either optical combination or disposition and the focal plane.

2. By placing the upper bearing of the polar axis below instead of above the cross tube of either disposition, all the mechanical conditions that M. Lœwy has used can be advantageously varied.

3. The use of the floating polar axis described by me in the May number of the *Monthly Notices* of the Royal Astronomical Society enables this to be done.

4. The shelter of the observer can then be quite detached from and independent of the telescope.

In the description of the floating polar axis referred to above, I mention its suitability for that disposition where one large and one small mirror is used.

My reason for not then mentioning the second disposition (that in which two large plane mirrors are used, one of these being perforated) to which this polar axis is most particularly adapted, was fear of stepping too far at once, as, apart from the additional difficulty of making a large plane perforated mirror, there seemed to me to be an element of risk and uncertainty in its use. After reading this article by M. Lœwy, I think there may not be much in my objections, but I cannot quite satisfy myself. In dealing with the support of the large plane mirror in the disposition that I allude to in the description of the polar axis, I contemplated such an arrangement for it as I have in use with my three-foot mirrors, this answering, as far as I have been able to see, perfectly, in eliminating flexure, and as the back of this large plane mirror would never wholly leave its supports, there would not be any fear of flexure here; the other mirrors offer no difficulty as they are practically as in an ordinary *Newtonian* telescope. The support of the large plane perforated mirror, when used for any latitude higher than 45°, is not easily obtained; it must rest on a rim touching the face all round, hence unless it could be hung up from the back in some way it might bend down and spoil the image.

It may be that the slight angle it would make would not bring in flexure of an injurious kind, and this could be determined by actual experiment beforehand, but at present it is an open question.

If it is not a difficulty, then I should agree with M. Lœwy that this is the best disposition for many reasons—it dispenses with the supports of the small mirror that cause diffraction rays, not objectionable to the observer except on bright objects, but very much so in a photograph, where they can impress themselves from an eighth or ninth magnitude star with any exposure that would be used for a nebula; it gives better support to the concave mirror: difficulties in connection with the reversal of the instrument do not come in with such force, and, most important of all, with such a polar axis as I have described, the focal plane might be kept very close behind the large perforated mirror, giving advantages of the greatest importance from many points of view.

The covering of the mirrors by a plate of glass has already been suggested and tried, but in a way that determined nothing. It is a capital thing to do; only experiment could really decide. Certainly flexure could be got over by air pressure, and it would be worth any trouble to get it, if not injurious to the image.

Ealing, August A. AINSLIE COMMON

Earthquakes in Japan

IN the one hundred and seventy-first volume of the "Konrui Shinko-Kushi," one of the oldest and finest works on Ancient Japan, there are tables giving the number, intensity, and remarkable characteristics of all the earthquakes which occurred in Japan between the years 416 and 886 A.D. Unfortunately, the few extant copies of this most important compilation are all more or less in a fragmentary condition. It is, however, evident from the context that the author intended to, or actually did, enumerate many more of these natural phenomena, and it is highly probable that many of his original notes have been lost with the rest; but even as it stands the work is of undoubted importance, now that the Seismological Society of Japan has been doing all in its power to bring forth the ancient records which refer to the great earthquakes of the past. As every one knows, Japan is the very hearth of earthquakes; in 1854 more than 60,000 people lost their lives in consequence of one of these great terrestrial catastrophes, and it has been calculated that from ten to twelve earthquakes, each lasting several seconds, occur every year, besides numerous others of too slight a nature to be worthy of remark.

The earthquakes mentioned in the work under consideration begin with that which took place in the fifth year after the coronation of Inkio Tenno (A.D. 416), and end with the one in the fifth year of Koko Tenno (A.D. 886). Earthquakes occurred during this period of 470 years on 640 days, but that by no means gives the probable total. It seems that those which are noted on the 640 days were all of sufficient importance to deserve particular mention. The great care taken by the compiler in his tables is evident from the fact that the exact date and time of each earthquake is given. Kiyoto was then the capital of Japan, and most of the earthquakes mentioned took place in the then Imperial City, 626 out of the total 640. Those not felt in Kiyoto are spoken of only when unusually intense, in which case the exact locality and amount of damage caused are given. Quite recently the vernacular Japanese press, in consequence of some lately published returns bearing on the subject, has devoted considerable attention to investigating the annals of the "Konrui-Shinko-Kushi," in hopes of being able to ascertain if earthquakes of certain intensity recur at certain periods, in fact, they have attempted to prove that earthquakes run in well-defined cycles. This is by no means a novel nor even very modern idea. Wernich, in his "Geographische-medicinische Studien," says that severe earthquakes occur in Japan every twenty years. In a footnote he adds:—"I am unable to adduce any natural or physical proofs in behalf of this hypothesis. And yet the Japanese earthquakes can be very readily explained by the theory of 'periodical phenomena.' They are commonest at the times of the highest tides, and in the months of January, April, and October."

Whatever may be the truth of the suppositions and theories, the Japanese journals, both the scientific and the dailies, have gone to work by accepting the periodicity of these phenomena. Taking ten years as the divisor, they divide the time between A.D. 628 (when the records begin to be more trustworthy) and A.D. 886 into twenty-six periods. The following table is the result:—

Periods	Earthquake days	Periods	Earthquake days	Periods	Earthquake days
•	0	10	6	19	3
2	3	11	5	20	56
3	0	12	29	21	39
4	1	13	3	22	18
5	2	14	0	23	104
6	15	15	11	24	87
7	1	16	22	25	95
8	0	17	10	26	100
9	3	18	9		

It is very evident from the foregoing that the records are far from being as exact as could be desired with regard to the earlier centuries, or else that the physical condition of the country in 886 was totally different from that of 628 A.D. But to return to the table, it will be seen that the intervals between the periods in which earthquakes were most frequent are as follows:—40 years between the 2nd and 6th periods, 60 years between the 6th and 12th, 40 years between the 12th and 16th, 40 years between the 16th and 20th, and 30 years between the 20th and 23rd. Acting on the supposition that one period of unusual frequency of earthquakes has been left unrecorded, the average length of the intervals is estimated at 35 years. Following the author's explanatory notes, a still more correct table can be deduced, by means of which the cycle of earthquake intensity is finally put at 33·3 years. A further deduction is made that earthquakes of a disastrous nature occur once every 59 years, so the next great catastrophe may be expected in 1913.

As the notes of the compiler give the date of each earthquake between the above-mentioned years, it appears that earthquakes used formerly to be most frequent in August, most severe in May and November, and followed or preceded by violent hurricanes, electric storms, and the like in January; 55 per cent. of all Japanese earthquakes occurring during the warm season.

Yokohama F. WARRINGTON EASTLAKE

"Udschimya sericaria," Rond., a Fly Parasitic on the Silkworm

I HAVE been engaged during the past year in tracing the life-history of *Udschimya sericaria*, Rond., and have succeeded in making it out completely. I send you a short account of it, hoping that it may not be entirely uninteresting to your readers. As you are no doubt aware, in Japan and China the maggot of this fly does great damage every year to the larvæ and pupæ of the silkworm, sometimes 80 per cent. of the caterpillars and pupæ being killed. The knowledge of its life-history would therefore be of great economic interest as furnishing the scientific basis for guarding against this parasite. Strange as it may seem, no one has, however, until recently, made any systematic observations on the matter.

In 1874 my father, Mr. N. Sasaki, who was the first to study this insect, found its larva in the main trunk of the trachea of the silkworm, just inside the stigma, and finally concluded that the

maggot gained this place by entering through the stigma from outside.

My investigations extend from April 1883 to June of this year, and are briefly summed up as follows:—

Udschimya sericaria appears generally in the middle of April, and attains maturity in the beginning of May, at the time when mulberry-trees expand their spring leaves. The female flies, flying in bushes of mulberry-trees during the months of May and June, deposit their eggs on the under surface of the leaves in close contact with the mid-rib, or else with the fine ramified veins.

The eggs are nearly oval in shape, tapering at one end, and rounded at the other. They are very small in size, measuring 0·18 mm. in length, and 0·13 mm. in breadth, and generally convex on the upper and flat on the under surface. The upper convex surface, which is coloured blackish-brown, has a lustre, and is marked out into hexagonal areas; while the lower flat surface, which is coloured grayish-brown, lacks lustre, and is only faintly marked out into hexagonal areas. The whole egg is enveloped with a sticky substance, which fixes it firmly with its flat side on the under surface of the leaves.

When the leaves on which the eggs are thus deposited are given to the silkworms, they eat them whole along with the leaves, without crushing them at all. At one to six hours after the eggs are taken, they are hatched out near either end of the digestive canal, and a tiny white maggot comes into existence. After a while the maggot passes out of the alimentary canal through the mucous membrane, with the aid of its horny hooked tooth and of setæ provided on each segment, and enters directly into one of the nervous ganglia found just under the digestive canal. A thin transparent membrane which envelops the ganglion becomes a protecting sac, inside which the maggot lives, and takes nerve-cells as its food. As it grows in size, this sac gradually enlarges, and finally rupturing, the maggot passes out into the body-cavity. At this time it measures five to six millimetres in length.

The maggot now seeks the main stem of the trachea, which forms a kind of chamber just inside the stigma of the silkworm, and enters into it by making an opening with its hooked tooth. It now sticks its head out into the body-cavity of the silkworm through the opening by which it entered, and takes fat as its food. Its posterior end, which is provided with two large spiracles, is directed towards the stigma, and thus the maggot respires the air which passes in through the latter.

As the maggot grows, this newly-formed chamber in which it rests also becomes larger, and the opening through which the anterior end of the maggot is projected out into the body-cavity of the silkworm becomes wider and wider, until the chamber assumes the shape of a cup. Around this cup a large amount of fat is fixed by the maggot, probably with a watery fluid it secretes of alkaline reaction, and thus the wall of the cup increases in thickness and becomes very tough. The wall is always coloured dark brown, owing probably to the fæces of the parasite and to the action of the secretion upon the fat in the wall of the cup. In this position the maggot attains maturity; it then crawls out through an opening it makes at any portion of the body of its host. If, however, the growth of the maggot has been slow, it may be found in the trachea of the silkworm after it has changed into a pupa.

In either case, whether the larvæ or the pupæ have the parasite in the trachea, the space around the stigma, inside which the maggot is lodged, is always marked with a large dark brown patch, so that the presence of the maggot is easily recognised by looking at the stigma.

If a larva or a pupa of the silkworm is once infested by this parasite, its fate is sealed, and the cocoons made by the infested caterpillars are usually thin, and of much less value.

Those maggots which become mature in the pupæ of the silkworm crawl out of the cocoon by making a round opening at one pole, and such perforated cocoons are entirely useless for reeling silk.

The mature free maggot, coloured light yellow, is very active, and searching for the corner of the case in which they are kept, or crawling deep into the ground, changes soon into a black, cylindrical pupa. There the pupa rests through the winter, and in the following spring a perfected fly hatches out by breaking open the pupa-case.

A detailed account with suggestions for the remedies will soon be published in a *Memoir* of the University of Tokio.

Singular Instance of Instinct

AMONG the insects very common to Victoria is one popularly known as the mason-fly. In form it is very like a gigantic hornet; the wings and legs are of an orange colour, as is also the abdomen, which is decorated with broad black stripes. It has a strange habit of building its nest, composed of tempered mud, in keyholes. Mr. Ellery, F.R.S., the Government Astronomer, tells me that this same fly often commences to build within the tubes of their astronomical instruments. The nest is rather peculiar. A layer of mud is first laid down, and a certain number of eggs are laid. Then follows another layer of mud; on this are deposited a number of young spiders, paralysed but not killed. Another layer of mud, more eggs, then mud, then spiders again, and so on, until the nest is complete. The spiders are evidently stored up as food for the grubs, as soon as hatched, an arrangement already known to naturalists. This fly has a very fierce aspect, and its nature evidently does not belie its looks. It flies about with great liveliness, and when alighting, its long black antennæ are kept in a state of constant motion. Its favourite food seems to be spiders, which it is in the habit of seeking for under the bark and in holes in the trunk of the Eucalyptus. In order to catch them it burrows under the loose bark, and in a few seconds generally issues forth again with some larg or smaller prey between its mandibles. The enormous bulk of some of the victims does not appear to intimidate it in the least. Even the gigantic so-called tarantula (vulgarly triantelope) is fearlessly attacked. I was one day walking through a suburban park near Melbourne, and saw one of these flies suddenly pounce down on the back of a large tarantula some five inches in breadth, measuring from the ends of the legs. The huge arachnidian succumbed at once. Resistance with an adversary in such a position was altogether out of the question, the only resource being to die, like Cæsar, becomingly. I watched the fight, or rather the murder, for some minutes, and then touching the assailant with the point of my umbrella, drove it away. It only flew, however, to a short distance, and then returned, flying so viciously round that I fully expected I should be attacked. By flourishing the umbrella, however, I again drove it off, and it retired to a distance of about a hundred feet. I then left the spider, but afterwards went back, and found the mason-fly following up his victory as energetically as ever. I drove it away again, left the spot, and again returned to find the murderous work still going on. This was repeated some half a dozen times, and at last, taking out a book, I sat down on a seat resolving to see what would happen. The fly did not reappear for nearly a quarter of an hour, and I thought it had altogether departed. A small ditch ran beside the pathway, and, turning my eyes in that direction, I noticed the mason-fly peeping through some blades of grass growing on the edge. It was evidently waiting for me to leave the spot in order to secure the full advantages of its victory.

It may be mentioned that the tarantula is a great coward. Some of our large spiders, if placed on an ants' nest, will "run amuck" through the crowd, nipping with their immense mandibles scores of their assailants who may approach them. They will do this several times in succession, and generally get away. The tarantula, however, if placed in such a position, yields at once, and, gathering up its long legs, expires with all dignity. I have tried the experiment many times, when a run of six inches would have secured the freedom of the tarantula, but even in these cases no effort was ever made to escape. One species of spider, living under the bark of trees, the skin of the abdomen of which is very soft, often proves a match for the ants, not by fighting, but by stratagem. He plays his enemies a thoroughly Parthian trick, throwing out a number of webs, which completely entangle them. This same spider, if thrown into a pool of water, similarly throws out threads of web, and, these being wafted to the shore, and adhering to an overhanging branch, enable the spider to reach the land.

Przevalsky's Horse

IT seems worth while to point out the close resemblance between the figure of this horse in NATURE for August 21 and those found incised on antlers in the cave of La Madelaine, copied in Dawkins' "Early Man." There is the same massive head, the same hog-mane, absence of forelock, pointed ears, short body, and powerful legs, while there seems even an indication that the long hairs of the tail spring first from the middle of that

organ. In that from Cresswell Crags, as well as those from La Madelaine, the jaw is heavier than in the recent specimen.

Brosely, August 29 W. W. WATTS

"The Ores of Leadville"

MY attention has lately been drawn to a review in NATURE for April 17 of a work on "The Ores of Leadville and their Mode of Occurrence," by Mr. L. D. Ricketts, from which one would be led to suppose that all the facts mentioned were due to original investigation on the part of the author. Your reviewer does not state that which is acknowledged by the author himself, namely, that much of his information was obtained from the Report of the U.S. Geological Survey by Mr. S. F. Emmons, contained in the Second Annual Report, published a year previously.

A large atlas has lately been issued also by the U.S. Geological Survey completely illustrating the Leadville ore deposits, and an exhaustive monograph to accompany it is now in the printers' hands. I speak from an intimate knowledge of the subject, having taken part in the work, and should be much obliged by your inserting this correction without delay.

ERNEST JACOB,
Late Assistant Geologist U.S.G.S.

AUSTRALIAN ORCHIDS

THE seventh and last part of vol. i. of Fitzgerald's "Australian Orchids," and the first part of vol. ii. have lately reached us. The testimony we bore to the value and merits of this work in our notice of part 5, vol. i. (NATURE, vol. xxii. p. 53) we can now repeat, and with emphasis, as we can base it on an examination of all the parts at present issued.

Mr. Fitzgerald is an ardent admirer and disciple of Darwin—indeed what true lover of orchids is not?—and his work is dedicated to his memory "as a token of the veneration in which he holds that great naturalist and fearless expounder of science." The synopsis shows that twenty-eight genera and 104 species are illustrated and described in vol. i., each part containing ten folio lithographic plates. The drawings and dissections leave nothing to be desired in point of fulness, completeness, and accuracy, the latter especially being far more numerous and varied than in any similar work we are acquainted with. There is one point on which those who are responsible for the nomenclature of Australian orchids are entitled to decided praise. All but one of the genera and 90 out of the 104 species in vol. i. bear really descriptive names, instead of being christened after "enterprising," or rather advertising, nurserymen or vanity-stricken cultivators, which is unfortunately the fate of most of the new orchids introduced into England. A large proportion of the orchids as yet described in this work are natives of New South Wales, but a few are contributed by Western Australia, Queensland, South Australia, and Tasmania. The enormous importance of insects to the maintenance of orchids is shown by the fact that, out of 104 species described in vol. i., ten only are self-fertilising. But the curious point is noted by the author that "self-fertilising species always produce a far greater proportion of seed." The difficulty with which some genera undergo fertilisation is illustrated by an instance given where a splendid plant of *Dendrobium Hillii* in the Sydney Botanic Gardens, freely open to insects, did not produce a single seed, though covered with about 40,000 flowers on 190 spikes! In another case mentioned by the author he found a small caterpillar on a flower of *Dendrobium speciosum*, which had partly eaten an adjoining flower. He marked the latter, and the flower so marked was the only one on the entire plant which produced seed. There is strong evidence that many species are dependent, not simply on insects, but on some particular, perhaps local, insect for fertilisation. *Sarcochilus parviflorus* often produces seed capsules in its native habitat, the Blue Mountains; if removed to Sydney, it flowers well, but does not produce seed unless artificially fertilised. One question discussed by the author is the fertility of hybrid orchids. We believe that this question has been settled in English plant-houses, where hybrids have been proved to be fertile in the case of one genus (Cypripedium) at all events. This result is what Mr. Fitzgerald anticipates, on account of the facility with which species of the same genus may be cross-fertilised, however far apparently they may be removed from one another. As he says, "a repugnance to intermixture does not exist in this family as it does in others."

While terrestrial orchids are very numerous in Australia, epiphytal orchids are comparatively rare. The latter are more ordinarily denizens of the hot and moist forests of tropical or sub-tropical regions. Thus not more than one-fifth of the species illustrated in Mr. Fitzgerald's work are epiphytal, and these belong almost entirely to the genera Sarcochilus and Dendrobium the latter a genus of which there are probably two or three hundred species, mostly natives of Indo-Chinese regions, cultivated in this country. On the other hand, the author says:—"The centre of the terrestrial" (orchids) "may, I think, be placed in Sydney, where, within the radius of a mile, I have obtained 62 species of orchids, 57 of which were terrestrial a number that could not, I believe, be equalled in any part of the world within a similar area."

The plates are accompanied by full descriptions giving curious and interesting details as to the methods of insect-fertilisation, and describing localities, surroundings, conditions of growth, &c. Notwithstanding the help derived from this source, Australian orchids have not, with some few exceptions, proved readily amenable to cultivation in this country. While it is comparatively easy to reproduce climates resembling those of the damp, shady, and hot valleys of the Amazon or of Burmah, or of the moist, cloud-covered, and cool slopes of the Andes or the Himalayas, it is very difficult to reproduce the dry, hot, and sunny conditions favourable to most of the terrestrial orchids of Australia. We shall therefore probably continue to know these for some time at least mainly from Mr. Fitzgerald's book. We doubt whether, excellent and obviously faithful as his drawings are, and carefully as they are coloured, the use of toned paper is judicious. It imparts a muddiness to the tints, as, for example, in the drawing of the beautiful Dendrobes, Phalænopsis, and Superbiens, part 7, vol. i., and part 1, vol. ii., where neither foliage nor flower have the clear bright colours natural to them.

Before concluding this notice of a work which devotes much attention to the curious and interesting study of orchid fertilisation, we might refer for a moment to the patience, care, and intelligence with which the raising of hybrid orchids is being prosecuted in this country, especially in the nursery of Messrs. James Veitch and Sons. In one genus, that of Cypripedium, the hybrids bids fair already to outnumber the known natural species, as well as to rival them in interest and beauty. The closely allied genera Cattleya and Lælia, which are distinguished only by the number of their pollen masses, have proved susceptible of cross-fertilisation, and have produced several intermediate hybrids of great beauty. It may well be said that patience is necessary for this work, for *Cattleya exoniensis*, the offspring of *Cattleya Mossiæ* and *Lælia purpurata*, did not flower until seventeen years after the seed had germinated. Even now it is only propagated by subdivision. The union of the genera Calanthe and Limatodes was more speedily fruitful; and the beautiful *Calanthe Veitchii*, especially valuable horticulturally, from its winter-flowering habit, is known in most gardens.

Few who have devoted themselves to the study or to the cultivation of orchids have failed to become greatly interested in this remarkable family. Their singular

structure, their extraordinary variety and diversity, their beauty, form great attractions. To these may now be added the interest, indeed excitement, to be obtained by intelligent and judicious cross-fertilisation. Altogether we need not wonder that the cultivation of orchids is spreading rapidly among the garden-loving people of these isles. For they interest equally the man of science and the gardener. We trust that Mr. Fitzgerald may bring his labour of love to a successful termination, and that descriptions of the orchids of other parts of the world, equally complete, accurate, interesting, and intelligent, may be taken in hand by botanists equally competent and enthusiastic. T. L.

GRINNELL LAND

THE following is the *Times* report of the paper read by Lieut. Greely at the British Association on Tuesday on some of the results of his recent Arctic expedition:—

Lieut. Greely stated that the geographical work of the Lady Franklin Bay Expedition covers nearly 3° of latitude and over 40° of longitude. Starting from lat. 81° 44′ N., long. 84° 45′ W., Lieut. Lockwood reached, on May 18, 1882, on the north coast of Greenland, lat. 83° 24′ N., long. 40° 46′ W. From the same starting-point he reached to the south-west, in May 1883, in Greely Fjord, an inlet of the Western Polar Ocean, in lat. 80° 48′ N., long. 78° 26′ W. The journey to the northward resulted in an addition to our charts of a new coast-line nearly 100 miles beyond the furthest point seen by Lieut. Beaumont of the Royal Navy. It also carried Greenland over forty miles northward, giving that continent a much greater extension in that direction than it had generally been credited with. The furthest point seen on the Greenland coast was estimated at about lat. 83° 35′ N., long. 38° W. There were no indications that the furthest point seen was the northern termination of Greenland. The newly-discovered coast resembled in many respects that of Southern Greenland; the mainland was intersected by many deep fjords, with numerous outlying islands. The interior of the country, as seen from an elevation of some 2000 feet, consisted of confused masses of mountains, eternally snow-clad or covered with ice-caps. The fjords presented to the eye nothing but broad, level expanses of snow and ice, being devoid of any marked ice-foot, floebergs, pressed-up hummocks, or any other indications tending to prove their direct connection with the Spitzbergen Sea. In general, the immediate coast was high, rugged, and precipitous; the formation very like that around Discovery Harbour—schistose slate, with a sprinkling of quartz. The vegetation resembled closely that of Grinnell Land. Among the specimens brought back is the Arctic poppy. Several saxifrages were identified above the 83rd parallel. Traces of the Polar bear, lemming, and Arctic fox were seen. A hare and ptarmigan were killed at the furthest north, and the snow bunting was heard. A remarkable fact noted was the existence of a tidal crack—so called for lack of a better name—which extended from Cape Bryant along the entire coast, running across various fjords in a direct line from headland to headland, varying from one yard to several hundred yards in width. Inside the crack, rough hummocky ice was but rarely seen, while outside prevailed the palæocrystic ice, over which Commander Markham struggled so manfully and successfully in his wonderful journey of 1875, midway between Capes May and Britannia. A sounding was made, but no bottom was found at 800 feet. Apparently no current existed. It may be well to state that the latitude of the furthest northern point, Lockwood Island, was determined by a set of circum-meridian and sub-polar observations, which were reduced by the Gauss method. The latitude of Cape Britannia and several other points was determined by circum-meridian observations. It affords me pleasure to testify to the accuracy of Lieut. Beaumont's maps; the only correction made places Cape Britannia a few miles south and Cape May a few miles west of their assigned positions. These points were located by Lieut. Beaumont from bearings. His comparative exactness was remarkable considering the disadvantages under which he laboured. The journeys made by Lieut. Lockwood and myself across Grinnell Land into its interior revealed striking and peculiar physical conditions which have been hitherto unsuspected. Between the heads of Archer and Greely Fjords, a distance of some seventy miles, stretches the perpendicular front of an immense ice-cap, which follows closely from east to west the 81st parallel. Its average height was not less than 150 feet. The undulations of the surface of the ice conformed closely to the configuration of the country, so that the variations in the thickness of the ice-cap were inconsiderable in about sixty miles. But two places were found where the slope and face were so modified as to render the ascent of the ice possible. This ice-cap, extending southward, covers Grinnell Land almost entirely from the 81st parallel to Hayes Sound, and from Kennedy Channel westward to Greely Fjord on the Polar Ocean. The glacier discharging into Dobbin Bay is but an offshoot of this ice-cap. Without doubt glaciers can be found at the head of every considerable valley debouching into Richardson, Scoresby, or other bays. Several valleys which were visited during the retreat southward displayed at their entrances evident signs of such occupancy in the past. In July I was fortunate enough to ascend Mount Arthur, the summit of which is 4500 feet above the sea. The day was very clear; to the northward of Garfield Range a similar ice-cap appeared to view, from which extensive glaciers projected through every mountain gap. One of these, Henrietta Nesmith Glacier, had been visited by me in the preceding April, and was found to have a perpendicular face of about 200 feet. It discharged into a small bay, part of Lake Hazen. Gilmar, Abbé, and other glaciers feed the streams which empty into that lake. Similarly glaciers were found at the head of the rivers discharging into St. Patrick and Lincoln Basins, Norris Bay, and Discovery Harbour. From these indications I estimate the northern ice-cap of Grinnell Land as not far from 6000 miles in area. This southern limit closely coincides with the 82nd parallel. The country between the 81st and 82nd parallels, extending from Kennedy and Robeson Channels to the Western Polar Ocean, was found in July entirely free from snow, except on the very backbone. In over 150 miles travel into the interior my foot never touched snow. Vegetation abounded, being exceedingly luxuriant as compared with Cape Hawkes, Cape Sabine, or other points further south visited by me. Dead willow was found in such abundance as to serve for fuel in more than one instance. Willow, saxifrages, grasses, and other plants grew in such profusion as to completely cover large tracts of ground. These valleys afford excellent pasturage for musk cattle, which feed towards the sea coast during summer, but withdraw to the interior as winter advances. I frequently noted evidences of recent elevation above the sea of the region now free from ice-cap. Such indications consisted of raised beaches, marine shells, and driftwood. At one place the trunks of two large coniferous trees were found in such a state of preservation as to allow of their use for fuel. It seems probable that these ice-caps were originally united. It is certain that both the northern and southern ice-caps have recently retreated, even if such a process is not going on now. Along the frontier of the southern ice were found many small glacial lakes and moraines. To the north, Lake Hazen for some fifty miles borders the ice-cap. In front of Henrietta Nesmith Glacier there were three parallel moraines. Between the face of the glacier

and the main lake at the junction of Lake Hazen and Ruggles River I discovered the remains of permanent Esquimaux huts. Many relics were obtained at that place and at various points along the southern shore of Lake Hazen, but no traces of any kind were found on the northern shore of the lake. It is perhaps worthy of remark that reindeer, which must have been plentiful in that country, have entirely disappeared, having either migrated or become extinct. In connection with the line of perpetual snow I may state that on Mount Arthur it was not far from 3500 feet above the sea. From barometrical measurements it appeared that the crest of Grinnell Land was above 2500 feet elevation in front of the southern ice-cap, 3000 feet near Mount Arthur.

THE BRITISH ASSOCIATION

So far as reports have reached us, the Montreal meeting has been a brilliant success, at least from the social point of view. The enthusiasm of the reception by the Canadians could not have been greater, and that enthusiasm, we are glad to notice, has met with a cordial response from the 800 members of the Association who went to Montreal. From the ample reports in the *Times* it is evident that, notwithstanding the many outside attractions devised by the hosts of the Association, the work in the Sections has in quantity and quality been up to the average. The proceedings began on Tuesday week with an address from the Mayor and Corporation of Montreal, and on Wednesday the Governor-General, Lord Lansdowne, welcomed the Association in a warm speech, in which the right keynote was struck. "If," he said, "you selected within the British Colonial Empire a spot for your meeting, you could not have selected a colony which better deserved this distinction either in respect of warmth of affection for the mother country, or the desire of its inhabitants for the diffusion of knowledge and culture. In a young country such pursuits are conducted in the face of difficulties, competition with material activity necessarily absorbing the attention of a rapidly developing community. We may claim for Canada that she has done her best, and has spared no pains to provide for the interests of science in the future. She has scientific workers known and respected far beyond the bounds of their own nation." Lord Lansdowne spoke warmly of the honour conferred upon Principal Sir John Dawson, who is more responsible than any other single person for the Association's visit. "We regard," he said, "the knighthood Her Majesty has bestowed upon him as an appropriate recognition of his distinguished services, and an opportune compliment to Canadian science. But the significance of this meeting is far greater than if measured merely by the addition it will make to the Empire's scientific wealth. When we find a society which for fifty years has not met outside the British Islands transferring its operations to the Dominion; when we see several hundred of the best-known Englishmen arriving here, mingling with our citizens and dispersing over this continent; when we see in Montreal the bearers of such names as Rayleigh, Playfair, Frankland, Sanderson, Thomson, Roscoe, Blanford, Moseley, Lefroy, Temple, Bramwell, Tylor, Galton, Harcourt, and Bonney, we feel one more step has been taken towards the establishment of that closer intimacy between the mother country and her offspring which both here and at home all good citizens of the Empire are determined to promote."

In introducing Lord Rayleigh as President, Sir William Thomson said:—

"It would have been a well-earned pleasure for my friend Prof. Cayley had he been able to visit Montreal, to introduce Lord Rayleigh to-night as his successor in the office of President of the British Association. Prof. Cayley has devoted his life to the advancement of pure mathematics, and it is peculiarly appropriate that he should be followed in his honourable post by one who has made the brilliant applications of mathematical power to the discovery and illustration of natural phenomena with which Lord Rayleigh has enriched physical science. Lord Rayleigh's optical researches are of great value—notably his profound and searching mathematical investigation of the blue sky and the polarisation of light by reflection. His book on 'Sound' is the greatest and most important work which has yet appeared on the subject. His determination of the ohm, which constitutes the accurate foundation for the great modern science of electrical measurement, is of supreme importance not only in the scientific laboratory but in all practical applications of electricity, as in the telegraph cable factory and the signalling station, in electrical engineering works, in every practical application of electric light, electro-metallurgy, and the electrical transmission of power. With much pleasure I resign the chair for Prof. Cayley, and introduce Lord Rayleigh as President of the British Association."

The Royal Society of Canada presented an address of welcome to the Association, and the American Association sent a cordial invitation to the members to attend the meeting at Philadelphia. Over 200 were to go, leaving Montreal by special train this morning.

A brilliant reception was given on Thursday night by the Governors, Principal, and Professors of McGill University, and Saturday was devoted entirely to excursions. Prof. Lodge's lecture on "Dust" on Friday night was both scientific and practical, and appears to have been a great success. He did well to speak strongly to a practical people of the rewards of pure scientific research, though we trust that one result of the meeting will be to open the eyes of the Canadians to the utility of substantially encouraging such research.

One of the most notable incidents of the meeting seems to have been the reception given to Prof. Asa Gray in the Biological Section, where he read a paper on North American botany, one of the most remarkable papers, Prof. Moseley stated, ever read in that Section. When Prof. Gray rose to reply, he received a perfect ovation.

The Corporation of McGill University, in commemoration of the British Association meeting at Montreal, were to confer, at the closing meeting yesterday, the honorary degree of LL.D. upon the following prominent representatives of science: The President, Lord Rayleigh; the following Vice-Presidents: the Governor-General, Lord Lansdowne; Sir John A. Macdonald, Sir Lyon Playfair, and Prof. Frankland; the General Secretaries, Capt. Douglas Galton and Mr. A. G. Vernon Harcourt; the Secretary, Prof. Bonney; the Sectional Presidents, Sir William Thomson, Sir Henry Roscoe, Mr. W. T. Blanford, Prof. Moseley, General Sir J. H. Lefroy, Sir Richard Temple, Sir Frederick Bramwell, and Dr. E. B. Tylor; also upon Prof. Daniel Wilson, President of Toronto University and the leading Canadian archæologist; Prof. Asa Gray of Harvard, the leading American botanist; and Prof. James Hall, the State Geologist of New York.

Lieut. Greely made his appearance in the Geographical Section on Tuesday, and gave a detailed account of the geographical and scientific results of his recent Arctic expedition. His paper, however, was no mere sensation; what he told the meeting of the condition of Grinnell Land is of real scientific value. On another page will be found the report of Lieut. Greely's paper.

One practical result of the Montreal meeting is that the Association will offer a gold medal in the Department of Applied Science in McGill University as a memento of the visit. Moreover, Mr. Blanford proposed in the Geological Section that as some return for the way in which they had been received the members should contribute for the formation of science scholarships in McGill College.

SECTION C

GEOLOGY

Opening Address by W. T. Blanford, F.R.S., Sec.G.S., F.R.G.S., President of the Section

In commencing an address to the Geological Section of the British Association on the first occasion on which that body has met outside of the British Islands I feel much difficulty. Amongst the eminent geologists who have filled the post which you have done me the honour of calling upon me to occupy for the present year there are several who would have been able, from their knowledge of both European and American geology, to treat with authority of the many points of interest elicited by comparison of geological phenomena on opposite sides of the Atlantic Ocean. My own experience has been chiefly derived from the distant continent of Asia, and I have not that intimate acquaintance with the geology of Europe, nor that knowledge of the progress of geological research in America, which would justify my entering upon any comparison of the two continents. It has, however, occurred to me that, amongst the questions of wide importance connected with the correlation of strata in distant parts of the world, there is one to which some interesting contributions have been made by the work of the Geological Survey of India, and by the geologists of Australia and South Africa, and that a short time might be profitably devoted to a consideration of a few remarkable exceptions to the rule that similarity of faunas and floras in fossiliferous formations throughout the surface of the world implies identity of geological age.

It has probably occurred to other geologists here present, as it has to myself, to be engaged in examining a country the geology of which was absolutely unknown, and to feel the satisfaction that attends the first discovery of a characteristic fossil form. A clue is at once afforded to the geology of the region; one horizon at least is believed to be determined, and from this horizon it is possible to work upwards and downwards until others are found.

It is, therefore, of especial importance to those engaged in geological exploration to satisfy themselves whether the conclusion is correct that identity, or close specific similarity, amongst fossil forms, is a proof that the beds containing them are of the same geological age. It has been pointed out by some of the most careful thinkers, and especially by Forbes and Huxley, that a species requires time to spread from one area to another, that, in numerous cases, a migratory specific form must flourish in the region to which it has migrated, after it has died out in its original birthplace; and that the presence of the same species in two deposits at distant localities may rather tend to indicate that both were not formed simultaneously. Huxley, as is well known, invented the term "homotaxis" to express the relations between such beds, and to avoid the possibly misleading expressions "geological synchronism," and "contemporaneous origin."

Despite such cautions, however, it still appears to be generally assumed by palæontologists that similarity between faunas and floras is evidence of their belonging to the same geological period; that the geological age of any formation, whether marine, fresh-water, or subaerial, can be determined by a comparison of its organic remains with those of other deposits, no matter how distant, of which the position in the geological sequence is ascertained: in short, that homotaxis of marine, fresh-water, and terrestrial forms implies geological synchronism.

That, as a general rule, homotaxis affords evidence that beds exhibiting it belong approximately to the same geological period appears supported by a large amount of evidence. But there are some startling exceptions. I propose to notice a few typical instances, several of them Indian, in which the system of determining the age of various formations by the fauna or flora has led to contradictory results, before attempting to show wherein the source of the error appears to lie. Nothing would be gained and much time would be lost by entering upon the details of all the cases known, even if I were able to give authentic particulars, which is doubtful. It will be sufficient to cite some characteristic examples, concerning the details of which satisfactory evidence is forthcoming.

Pikermi Beds.—There are but few fossiliferous deposits on the face of the earth that have attracted more attention than the Pikermi beds of Greece. In one of the most classical and famous sites of the world, a few miles east of Athens, just where

> The mountains look on Marathon,
> And Marathon looks on the sea,

some red, silty beds occur, abounding in vertebrate remains. Some of the bones were described by Wagner and others, but for a complete account of the fauna we are indebted to Prof. Albert Gaudry, who has himself collected by far the greater portion of the remains hitherto procured. The following is a list of the genera determined; it is unnecessary to give the specific names:—

MAMMALIA.

Primates.—*Mesopithecus*, 1 sp.
Carnivora.—*Simocyon*, 1; *Mustela*, 1; *Promephitis*, 1; *Ictitherium*, 3; *Hyæna*, 1; *Lepthyæna*, 1; *Hyænictis*, 1; *Felis*, 4; *Machærodus*, 1.
Proboscidea.—*Mastodon*, 2; *Dinotherium*, 1.
Ungulata.—*Chalicotherium*, 1; *Rhinoceros*, 3; *Acerotherium*, 1; *Leptodon*, 1; *Hipparion*, 1; *Sus*, 1; *Camelopardalis*, 1; *Helladotherium*, 1; *Orasius*, 1; *Palæotragus*, 1; *Palæoryx*, 2; *Tragocerus*, 2; *Palæoreas*, 1; *Antidorcas* (?), 1; *Gazella*, 1; *Antilope*, 3; *Dremotherium*, 2.
Rodentia.—*Hystrix*, 1.
Edentata.—*Ancylotherium*, 1.

AVES.

Phasianus, 1; *Gallus*, 1; *Gen. gallinac. indet.*, 1; *Grus*, 1; *Gen. ciconidar. indet.*, 1.

REPTILIA.

Testudo, 1; *Varanus*, 1.

Of Mammalia alone there are known from this deposit 31 genera, of which 22 are extinct, and 35 species.

Now, this fauna is almost invariably in European works quoted as Miocene. Of the species found no less than 14—*Simocyon diaphorus*, *Ictitherium robustum*, *I. hipparionum*, *Hyæna eximia*, *Hyænictis græca*, *Machærodus cultridens*, *Mastodon turicensis*, *Dinotherium giganteum*, *Rhinoceros schleiermacheri*, *Hipparion gracile*, *Sus erymanthius*, *Helladotherium duvernoyi*, *Tragocerus amaltheus*, and *Gazella brevicornis*—are met with in other European deposits assigned to the Miocene period. It is true that one of these deposits at least—that of Eppelsheim—has been shown on stratigraphical grounds to be much more probably Pliocene than Miocene, and the position of other deposits has been determined by the kind of argument which, as I shall show, has proved misleading in the case of Pikermi itself. Nevertheless so general is the consensus of opinion amongst palæontologists, that the beds with *Hipparion* at Pikermi and elsewhere are quoted as especially included in the Miocene system by the French Committee of the International Geological Congress. Amongst English writers the Miocene age of the Pikermi beds appears generally admitted, as by Mr. Wallace (*Geographical Distribution of Animals*, i. p. 115), Prof. Boyd Dawkins (*Q. J. G. S.* 1880, p. 389), Mr. E. T. Newton (*Q. J. G. S.* 1884, pp. 284, 287, &c.), and many others. Prof. Gaudry himself is much more cautious; he classes the fauna as intermediate between Pliocene and Miocene, and only relegates it to Upper Miocene because that is the position assigned by other palæontologists to beds containing remains of *Hipparion*. However, in his subsequent works Prof. Gaudry has classed the Pikermi fauna as Miocene.

Now, the lowest of the beds with the vertebrate fauna at Pikermi were by Prof. Gaudry himself found to be interstratified with a band of gray conglomerate containing four characteristic *marine* Pliocene Mollusca—*Pecten benedictus*, Lam.; *Spondylus gaederopus*, L.; *Ostrea lamellosa*, Brocchi; and *O. undata*, Lam. It should be remembered that the Pliocene fauna of the Mediterranean area is the richest and most typical in Europe, and is as well known as any geological fauna in the world. It should also be remembered that the Pliocene beds are well developed in Greece at other localities besides Pikermi. Prof. Gaudry especially points out that the vertebrate remains, supposed to be those of Miocene animals, are deposited in a stratum overlying a marine bed of undoubted Pliocene age, and he proposes the following hypothesis to account for the presence of Miocene fossils in a Pliocene stratum. The remains found at Pikermi are, he thinks, those of animals that inhabited the extensive plains which in Miocene times extended over a considerable proportion of the area now occupied by the Eastern Mediterranean, and which united Greece to Asia; the plains were broken up by the dislocations that took place at the close of the Miocene period, and the animals escaped to the mountains, where they died for want of space and of food. Their bones were subsequently washed down by the streams from the hills and buried in the Pliocene deposits of Pikermi.

Prof. Gaudry evidently has no very profound faith in this hypothesis, and it is unnecessary to refute it at length. One fact is sufficient to show that it is untenable. However sudden may have been the cataclysm that is supposed to have broken up the Miocene plains of Attica, a very long period, measured in years, must have elapsed before the Pliocene marine fauna could have established itself. Now, the bones of mammals exposed on the surface decay rapidly; the teeth break up, the bones become brittle. It is doubtful if bones that had been exposed for only five or six years would be washed down by a stream without being broken into fragments; the teeth especially would split to pieces. The condition of the Pikermi fossils proves, I think, that they must have been buried very soon after the animals died, that they were not exposed on the surface for any length of time, and that they could not have been washed out of an earlier formation, and it appears to me incredible that the Pikermi mammals were not contemporary with the Pliocene Mollusca that occur in the same beds. In short, I cannot but conclude that the Pikermi mammals were Pliocene and not Miocene.

This view is entirely in accordance with the opinions of Theodor Fuchs (*Denkschr. K. Acad. Wiss. Wien*, 1877, xxxvii. 2e Abth. p. 1). He has given a good account of the geology of various places in Greece, and amongst others of Pikermi. He found, again, the conglomerate with Pliocene marine Mollusca interstratified with the basal portion of the mammaliferous beds, and he concludes (*l.c.* p. 30), that not only is it clear that these mammaliferous beds are of Pliocene age, but that a comparison of their geological position with that of the marine strata of the Piræus proves that the Pikermi beds occupy a very high position in the Pliocene, and are probably the highest portion of the system as developed in the neighbourhood.

Fuchs also shows that the principal Pliocene mammaliferous beds are of later date than the typical Pliocene (sub-Apennine) beds of Italy, and that some Mammalia found associated with the latter comprise forms identical with those of the Pikermi beds. In subsequent papers on the age of the beds containing *Hipparion* the same writer shows reasons for classing these strata in Italy, France (Vaucluse), and Germany as intermediate between Miocene and Pliocene. This leaves the difficulty unsolved, for he had shown the Pikermi beds to be high in the Pliocene system. They rest unconformably upon certain fresh-water limestones, clays, &c., containing plants and Mollusca, and classed by Gaudry as Miocene, but by Fuchs as Pliocene. Thus by both writers mammaliferous beds of Pikermi are referred to a considerably later geological horizon than those containing identical species in other parts of Europe.

It would require too much time to enter into the still more difficult question of the various plant-bearing beds in different parts of Europe and in Greenland containing a flora classed by Heer and others as Miocene. Gardner has given reasons for considering the Greenland beds Eocene; Fuchs, as just stated, is of opinion that the Greek beds are Pliocene. One point should be noted, that the more northern flora is considered older than the more southern, and it will be remarked that the same observation applies to the supposed Upper Miocene fauna of France and Germany and the Pikermi fauna of Greece.

Siwalik.—The next instance which I shall describe is another of the most important fossil mammalian faunas of the Old World, that found in the Upper Tertiary beds that fringe the Himalayas on the south. The name applied to this fauna is taken from one of the localities in which it was first found, the Siwalik (correctly, I believe, Shib-wala) hills, between the Deyra Dun and the plains north by east of Delhi. Bones of Siwalik Mammalia are found, however, throughout a considerable area of the Northern Punjab.

The Siwalik fauna has been worked out, chiefly by Falconer and Lydekker, the last-named being still engaged in describing the species. The following is a list of the genera found in the true Siwalik beds:—[1]

MAMMALIA.

PRIMATES.—*Palæopithecus*, 1 sp.; *Macacus*, 2; *Semnopithecus*, 1; *Cynopithecus*, 2.

CARNIVORA.—*Mustela*, 1; *Mellivora*, 2; *Mellivorodon*, 1; *Lutra*, 3; *Hyænodon*, 1; *Ursus*, 1; *Hyænarctus*, 3; *Canis*, 2; *Viverra*, 2; *Hyæna*, 5; *Lepthyæna*, 1; *Æluropsis*, 1; *Ælurogale*, 1; *Felis*, 5; *Machærodus*, 2.

PROBOSCIDEA.—*Elephas*, 6 (*Euelephas*, 1; *Loxodon*, 1; *Stegodon*, 4); *Mastodon*, 5.

UNGULATA.—*Chalicotherium*, 1; *Rhinoceros*, 3; *Equus*, 1; *Hipparion*, 2; *Hippopotamus*, 1; *Tetraconodon*, 1; *Sus*, 5; *Hippohyus*, 1; *Sanitherium*, 1; *Merycopotamus*, 1; *Cervus*, 3; *Dorcatherium*, 2; *Tragulus*, 1; *Propalæomeryx*, 1; *Camelopardalis*, 1; *Helladotherium*, 1; *Hydaspitherium*, 2; *Sivatherium*, 1; *Alcephalus*, 1; *Gazella*, 1; *Antilope*, 2; *Oreas* (?), 1; *Palæoryx* (?), 1; *Portax*, 1; *Hemibos*, 3; *Leptobos*, 1; *Bubalus*, 2; *Bison*, 1; *Bos*, 3; *Bucapra*, 1; *Capra*, 2; *Ovis*, 1; *Camelus*, 1.

RODENTIA.—*Mus*, 1; *Rhyzomys*, 1; *Hystrix*, 1; *Lepus*, 1.

AVES.

Graculus, 1; *Pelecanus*, 2; *Megaloscelornis*, 1; *Argala*, 1; *Struthio*, 1; *Dromæus*, 1.

REPTILIA.

CROCODILIA.—*Crocodilus*, 1; *Gharialis*, 3.

LACERTILIA.—*Varanus*, 1.

CHELONIA.—*Colossochelys*, 1; *Testudo*, 1; *Bellia*, 2; *Damonia*, 1; *Emys*, 1; *Cautleya*, 1; *Pangshura*, 1; *Emyda*, 1; *Trionyx*, 1.

PISCES.

Bagarius, 1.

Now, until the last few years, this fauna was classed as Miocene by European palæontologists as unhesitatingly as the Pikermi fauna still is, and in the majority of European geological works, despite the unanimous opinion of all the geologists who are acquainted with the sub-Himalayan beds, the Siwalik fauna is still called Miocene. The geologists of the Indian Survey, however, class the fossiliferous Siwaliks as Pliocene, on both geological and biological grounds. With regard to the latter, not only does the fauna comprise a large number of existing genera of mammals, such as *Macacus*, *Semnopithecus*, *Ursus*, *Elephas* (*Euelephas*), *Equus*, *Hippopotamus*, *Camelopardalis*, *Bos*, *Hystrix*, *Mus*, and especially *Mellivora*, *Meles*, *Capra*, *Ovis*, *Camelus*, and *Rhizomys*, but three out of six or seven clearly-determined species of reptiles, viz.—*Crocodilus palustris*, *Gharialis gangeticus*, and *Pangshura tectum*—are living forms now inhabiting Northern India, whilst all the known land and fresh water Mollusca, with one possible exception, are recent species.

These data, however, although very important and very cogent, belong to a class of facts that have led, I believe, in other cases to erroneous conclusions. The geological evidence is far more satisfactory, and it is not liable to the same objection.

The whole Siwalik fauna, as given above, has been obtained from the upper beds of a great sequence or system. Beneath the fossiliferous strata at the base of the North-West Himalaya there is an immense thickness, amounting in places to many thousands of feet, of sandstones, clays, and other beds, from none of which recognisable fossils have been procured. The first beds of known age that are met with below the mammaliferous Siwaliks are marine rocks belonging to the Eocene system.

But as we pass from the Himalayas to the south-west, along the western frontier of India in the Punjab, and onwards to the south in Sind, the same Siwalik system can be traced almost without interruption, and in the last-named country the lower unfossiliferous strata become intercalated with fossiliferous beds. In Sind the upper Siwaliks no longer yield any vertebrate remains that can be identified, but far below the horizon of the Siwalik fauna a few bones have been found, and the following mammals have been identified (*Pal. Ind.* ser. x.; *Rec. Geol. Surv. Ind.* 1883, pp. 82, &c.)—

CARNIVORA.—*Amphicyon palæindicus*.

PROBOSCIDEA.—*Mastodon latidens*, *M. perimensis*, *M. falconeri*, *M. pandionis*, *M. angustidens*, *Dinotherium indicum*, *D. sindiense*, *D. pentapotamiæ*.

UNGULATA.—*Rhinoceros sivalensis*, var. *intermedius*, *Acerotherium perimense*, *A. blanfordi*, *Sus hysudricus*, *Hyotherium sindiense*, *Anthracotherium silistrense*, *A. hyopotamoides*, *Hyopotamus palæindicus*, *H. giganteus*, *Hemimeryx blanfordi* *Sivameryx sindiensis*, *Agriochœrus* sp., *Dorcatherium majus*, *D. minus*.

EDENTATA.—*Manis* (?) *sindiensis*.

Although about one-third of the species above named have been found also in the upper Siwalik beds of the Punjab, it is unnecessary to point out in detail why the lower Siwalik fauna is clearly by far the older of the two. The absence of such living genera as *Elephas*, *Bos*, *Equus*, &c., and the presence of

[1] Lydekker, *J. A. S. B.* 1880, pt. 2, p. 34; *Palæontologia Indica*, ser. x. vols. i. ii. iii.; *Records Geol. Surv. India*, 1883, p. 81. I am indebted to Mr. Lydekker for some unpublished additions.

so many typically Middle Tertiary forms, such as *Dinotherium*, *Anthracotherium*, and *Hyopotamus*, shows a great change. The Mollusca tell the same tale. All the forms known from the upper Siwaliks, with one exception, are recent species of land and fresh-water shells now living in the area. Of seven fresh-water Mollusca (*Mem. Geol. Surv. Ind.* vol. xx. pt. 2, p. 129) found associated with the lower Siwaliks none appears to be identical with any living species, and only two are allied, one closely, the other more remotely, to forms now met with in Burmah, 30° of longitude further east.

Before proceeding with the argument, it is as well to call attention to the very important fact just mentioned. It has been asserted over and over again that species of *Mammalia* are peculiarly short-lived, far more so than those of *Mollusca*. In this case, so far as the evidence extends at present, one-third of the species of *Mammalia* survived the changes that took place, whereas not a single mollusk is found both in the upper and lower Siwaliks. It should be remembered that the recent molluscan river fauna of this part of India is very poor in species, and that we probably know a considerable proportion of that existing in Siwalik times.

The geological age of the lower Siwalik beds of Sind is shown by their passing downwards into marine fossiliferous beds, known as the Gáj group, of Miocene age, the following being the section of Tertiary strata exposed in the hills west of the Indus:—

		Ft.	
SIWALIK or MANCHHAR	Upper	5000 unfossiliferous	Pliocene
	Lower	3000 to 5000 fossiliferous	Upper Miocene or Lower Pliocene
GÁJ		1000 to 1500 fossiliferous	Miocene
NARI	Upper	4000 to 6000 unfossiliferous	Lower Miocene
	Lower	100 to 1500 fossiliferous	Oligocene
KHIRTHAR	Upper	500 to 3000 fossiliferous	Eocene
	Lower	6000 fossiliferous	

Clearly the lower Siwaliks of Sind cannot be older than Upper Miocene; therefore the upper Siwaliks, which are shown by both biological and geological evidence to be of much later date, must be Pliocene.

Gondwána System of India.—In the peninsula of India there is a remarkable deficiency of marine formations. Except in the neighbourhood of the coast or of the Indus Valley there is, with one exception (some Cretaceous rocks in the Nerbudda Valley), not a single marine deposit known south of the great Gangetic plain. But in Bengal and Central India, over extensive tracts of country, a great sequence of fresh-water beds, probably of fluviatile origin, is found, to which the name of Gondwána System has been applied. The uppermost beds of this system, in Cutch to the westward, and near the mouth of the Godávari to the eastward, are interstratified with marine beds containing fossils of the highest Jurassic (Portlandian and Tithonian) types.

The Gondwána system is a true system in the sense that all the series comprised are closely connected with each other by both biological and physical characters, but it represents in all probability a much longer period of geological time than do any of the typical European systems. The highest members, as already stated, are interstratified with marine beds containing uppermost Jurassic fossils. The age of the lowest members is less definitely determined, and has been by different writers classed in various series from Middle Carboniferous to Middle Jurassic. The Gondwána beds from top to bottom are of unusual interest on account of the extraordinary conflict of palæontological evidence that they present.

The subdivisions of the Gondwána system are numerous, and in the upper portions especially the series and stages are different in almost every tract where the rocks are found. The following are the subdivisions of most importance on account of their fauna and flora, or of their geological relations:—

Upper Gondwána	Cutch and Jabalpur	
	Kota-Maleri	
	Rájmahál	
Lower Gondwána	Panchet	
	Damuda	Ránigani and Kámthi
		Barákar
	Karharbári	
	Tálchir	

The upper Gondwánas, where best developed, attain a thickness of 11,000 feet, and the lower of 13,000 ft.

The Tálchir and Barákar subdivisions are far more generally present than any of the others.

Tálchir.—The Tálchir beds consist of fine silty shales and fine soft sandstone. Very few fossils have been found in them, and these few recur almost without exception in the Karharbári stage. The Tálchirs are principally remarkable for the frequent occurrence of large boulders, chiefly of metamorphic rocks. These boulders are sometimes of large size, 6 feet or more across, 3 to 4 feet being a common diameter; all are rounded, and they are generally embedded in fine silt.

Karharbári.—The Karharbári beds are found in but few localities. They contain some coal-seams, and the following plants have been met with (Feistmantel, *Palæontologia Indica*, ser. xii. vol. iii.):—

CONIFERÆ.—*Euryphyllum*, 1 sp.; *Voltzia*, 1; *Albertia*, 1; *Samaropsis*, 1.
CYCADEACEÆ.—*Glossozamites*, 1; *Noeggerathiopsis*, 1.
FILICES.—*Neuropteris*, 1; *Glossopteris*, 4; *Gangamopteris*, 4; *Sagenopteris*, 1.
EQUISETACEÆ.—*Schizoneura*, 2; *Vertebraria*, 1.

The most abundant form is a *Gangamopteris*. The *Voltzia* (*V. heterophylla*) is a characteristic Lower Triassic (Bunter) form in Europe. The *Neuropteris* and *Albertia* are also nearly related to Lower Triassic forms. The species of *Gangamopteris*, *Glossopteris*, *Vertebraria*, and *Noeggerathiopsis* are allied to forms found in Australian strata.

Damuda.—The Damuda series consists of sandstones and shales with coal-beds; the floras of the different subdivisions present but few differences, and the following is the list of plants found (*Pal. Ind.* ser. ii. xi. xii. vol. iii.):—

CONIFERÆ.—*Rhipidopsis*, 1 sp.; *Voltzia*, 1; *Samaropsis*, 1; *Cyclopitys*, 1.
CYCADEACEÆ.—*Pterophyllum*, 2; *Anomozamites*, 1; *Noeggerathiopsis*, 3.
FILICES.—*Sphenopteris*, 1; *Dicksonia*, 1; *Alethopteris*, 4; *Pecopteris*, 1; *Merianopteris*, 1; *Macrotæniopteris*, 2; *Palæovittaria*, 1; *Angiopteridium*, 2; *Glossopteris*, 19; *Gangamopteris*, 7; *Belemnopteris*, 1; *Anthrophyopsis*, 1; *Dictyopteridium*, 1; *Sagenopteris*, 4; *Actinopteris*, 1.
EQUISETACEÆ.—*Schizoneura*, 1; *Phyllotheca*, 3; *Trizygia*, 1; *Vertebraria*, 1.

The only remains of animals hitherto recorded are an *Estheria* and two Labyrinthodonts, *Brachyops laticeps* and an undescribed form formerly referred to *Archegosaurus*. The only European genus allied to *Brachyops* is of Oolitic age.

The most abundant of the above-named fossils are *Glossopteris* and *Vertebraria*. With the exception of *Noeggerathiopsis* all the cycads and conifers are of excessive rarity. More than one-half of the species known are ferns with simple undivided fronds and anastomosing venation.

For many years European palæontologists generally classed this flora as Jurassic.[1] This was the view accepted by De Zigno and Schimper, and, though with more hesitation, by Bunbury. The species of *Phyllotheca*, *Alethopteris* (or *Pecopteris*), and *Glossopteris* (allied to *Sagenopteris*) were considered to exhibit marked Jurassic affinities. It was generally admitted that the Damuda flora resembles that of the Australian Coal-Measures (to which I shall refer presently) more than it does that from any known European formation; but the Australian plants were also classed as Jurassic. There is no reason for supposing that the more recent discoveries of Damuda plants would have modified this view; the identification of such forms as true *Sagenopteris* and the cycads *Pterophyllum* and *Anomozamites* would assuredly have been held to confirm the Jurassic age of the beds. So far as European fossil plants are concerned, the Damuda flora resembles that of the Middle or Lower Jurassics more than any other.

One form, it is true, the *Schizoneura*, is closely allied to *S. paradoxa* from the Bunter or Lower Trias of Europe. Other plants have Rhætic affinities. But the connections with the Triassic flora do not seem nearly equal to those shown with Jurassic plants, and the reason that the Damuda flora has been classed as probably Triassic must be sought in the impossibility of considering it newer (Feistmantel, *Pal. Ind.* ser. xii. vol. iii. pp. 57, 129, &c.), if the next overlying stage is classed as Upper Trias or Rhætic, and in the close affinity with the underlying Karharbári beds, which contain several Lower Triassic types.

Panchet.—The uppermost series of the lower Gondwánas consists chiefly of sandstone, and fossils are rare. The most in-

[1] De Zigno, *Flora Fossilis Form. Ool.* pp. 50, 53; Schimper, *Traité de Paléontologie végétale*, i. p.645; Bunbury, *Q. J. G. S.* 1861, xvii. p. 350.

teresting are remains of *Reptilia* and *Amphibia*. The following is a list of the fossil animals and plants corrected to the present time:—

ANIMALS.

REPTILIA.

DINOSAURIA.—*Ancistrodon*, 1 sp.
DICYNODONTIA.—*Dicynodon* (*Ptychognathus*). 2.

AMPHIBIA.

LABYRINTHODONTIA.—*Gonioglyptus*, 2; *Glyptognathus*, 1; *Pachygonia*, 1.

CRUSTACEA.

Estheria, 1.

PLANTS.

CONIFERÆ.—*Samaropsis*, 1.
FILICES.—*Pecopteris*, 1; *Cyclopteris*, 1; *Thinnfeldia*, 1; *Oleandridium*, 1; *Glossopteris*, 3.
EQUISETACEÆ.—*Schizoneura*, 1.

The *Schizoneura* and the three species of *Glossopteris* are considered the same as Damuda forms. But with them are found two European Rhætic species, *Pecopteris concinna* and *Cyclopteris pachyrachis*. The *Oleandridium* is also closely allied to a European Rhætic form, and may be identical. The flora may thus be classed as typically Rhætic.

All the genera of *Labyrinthodonts* named are peculiar; their nearest European allies are chiefly Triassic. *Dicynodontia* are only known with certainty from India and South Africa, but some forms believed to be nearly allied have been described from the Ural mountains (Huxley, *Q. J. G. S.* xxvi. p. 48.). These fossils were obtained from rocks now referred to the Permian (Twelvetrees, *Q. J. G. S.* xxxviii. p. 500).

Upper Gondwánas.—The different series of the lower Gondwánas are found in the same area, resting one upon the other, so that the sequence is determined geologically. This is not the case with the upper Gondwána groups; their most fossiliferous representatives are found in different parts of the country, and the relations to each other are mainly inferred from palæobotanical data. Although, therefore, it is probable that the Rájmahâls are older than the Cutch and Jabalpur beds, and that the Kota-Maleri strata are of intermediate age, it is quite possible that two or more of these series may have been contemporaneously formed in regions with a different flora.

Rájmahál.—The comparatively rich flora of the lowest upper Gondwána series is contained in beds interstratified with basaltic lava-flows of the fissure-eruption type. The following are the genera (*Pal. Ind.* ser. ii.; Feistmantel, *Rec. G. S. I.* ix. p. 39) of plants found:—

CONIFERÆ.—*Palissya*, 2 sp.; *Cunninghamites*, 1; *Chirolepis*, 2; *Araucarites*, 1; *Echinostrobus*, 1.
CYCADEACEÆ.—*Pterophyllum*, 9; *Ptilophyllum*, 1; *Otozamites*, 3; *Zamites*, 1; *Dictyozamites*, 1; *Cycadites*, 2; *Williamsonia*, 2; *Cycadinocarpus*, 1.
FILICES.—*Eremopteris*, 2; *Davallioides*, 1; *Dicksonia*, 1; *Hymenophyllites*, 1; *Cyclopteris*, 1; *Thinnfeldia*, 1; *Gleichenia*, 1; *Alethopteris*, 1; *Asplenites*, 1; *Pecopteris*, 1; *Macrotæniopteris*, 4; *Angiopteridium*, 3; *Danæopsis*, 1; *Rhizomopteris*, 1.
EQUISETACEÆ.—*Equisetum*, 1.

The marked change from the lower Gondwána floras is visible at a glance; not a single species is common to both, most of the genera are distinct, and the difference is even greater when the commonest plants are compared. In the lower Gondwánas the prevalent forms are *Equisetaceæ* and ferns of the *Glossopteris* type, whilst in the Rájmahál flora cycads are by far more abundant than any other plants. The whole assemblage, moreover, is more nearly allied than are any of those in the lower Gondwána beds to European Mesozoic floras.

Of the Rájmahál plants (Feistmantel, *Pal. Ind.* ser. ii. pp. 143, 187; *Manual Geol. Ind.* p. 145) about fifteen are allied to Rhætic European forms, three to Liassic or Lower Jurassic (two of these having also Rhætic affinities), and six to Middle Jurassic (two having Rhætic relations as well. The flora must therefore as a whole on purely palæontological grounds be classed as Rhætic.

Kota-Maleri.—The deposits belonging to this series are found in the Godávari valley at a considerable distance from the Rájmahál hills in Bengal, the locality for the Rájmahál flora. Both Rájmahál and Kota-Maleri beds overlie rocks of the Damuda series. It is not quite clear whether the Kota beds, which contain fish, insects, and crustaceans, and the Maleri beds, in which remains of fish, reptiles, and plants are found, are interstratified, or whether the Kota beds overlie those of Maleri. That the two are closely connected is generally admitted.

From the Maleri beds the following remains have been collected:—

ANIMALS.

REPTILIA.—*Hyperodapedon*, 1 sp.; *Parasuchus*, 1.
PISCES.—*Ceratodus*, 3.

PLANTS.

CONIFERÆ.—*Palissya*, 2; *Chirolepis*, 1; *Araucarites*, 1.
CYCADEACEÆ.—*Ptilophyllum*, 1; *Cycadites*, 1.
FILICES.—*Angiopteridium*, 1.

From the Kota fresh-water limestone nine species of ganoid fish —viz. five of *Lepidotus*, three of *Tetragonolepis*, and one of *Dapedius* —have been described. An *Estheria*, a *Candona*, and some insects have also been found. The fish (*Pal. Ind.* ser. iv. pt. 2) are Liassic forms.

The Reptilia of the Maleri beds are, on the other hand, Triassic[1] and closely allied to Keuper forms. *Ceratodus* is chiefly Triassic (Keuper and Rhætic). The plants show relations with both the Rájmahál and Jabalpur floras, and, as the palæontological relations to beds in the same country are considered far higher in importance than those to deposits in distant regions, the Kota-Maleri beds are classed as intermediate between the Rájmahál and Jabalpur epochs.

Cutch and Jabalpur.—Jabalpur beds are found in Central India to the south of the Nerbudda Valley, and form the highest true Gondwána beds. The Cutch beds, as already mentioned, are found interstratified with marine deposits of uppermost Jurassic age far to the westward, a little east of the mouths of the River Indus. The similarity of the plant-remains in the two series has caused them to be classed together, but it is not certain that they are really of contemporaneous origin.

The following is a list of the Jabalpur plants (*Pal. Ind.* ser. xi. pt. 2):—

CONIFERÆ.—*Palissya*, 2 sp.; *Araucarites*, 1; *Echinostrobus*, 2; *Brachyphyllum*, 1; *Taxites*, 1; *Gingko*, 1; *Phœnicopsis*, 1; *Czekanowskia*, 1.
CYCADEACEÆ.—*Pterophyllum*, 1; *Ptilophyllum*, 2; *Podozamites*, 3; *Otozamites*, 4; *Williamsonia*, 1; *Cycadites*, 1.
FILICES.—*Sphenopteris*, 1; *Dicksonia*, 1; *Alethopteris*, 3; *Macrotæniopteris*, 1; *Glossopteris*, 1; *Sagenopteris*, 1.

Of these thirty species nine are regarded either as identical with forms found in the Middle Jurassic (Lower Oolitic) of England, or as closely allied.

The Cutch plants belong to the following genera (*Pal. Ind.* ser. xi. pt. 1):—

CONIFERÆ.—*Palissya*, 3 sp.; *Pachyphyllum*, 1; *Echinostrobus*, 1; *Araucarites*, 1.
CYCADEACEÆ.—*Ptilophyllum*, 3; *Otozamites*, 3; *Cycadites*, 1; *Williamsonia*, 1; *Cycadolepis*, 1.
FILICES.—*Oleandridium*, 1; *Tæniopteris*, 1; *Alethopteris*, 1; *Pecopteris*, 1; *Pachypteris*, 2; *Actinopteris*, 1.

Of the twenty-two species enumerated, four are identified with specific forms found in the Middle Jurassic of Yorkshire, and seven others are closely allied. The Cutch and Jabalpur beds, in short, are intimately related with European fossil floras, whilst the associations of Indian fossil plants found in the Rájmahál, Damuda, and Karharbári beds have no such close connection with Western types.

One interesting fact should be mentioned. The Cutch flora occurs in the upper part of the Umia beds, the lower beds of which contain *Cephalopoda* of Portlandian and Tithonian forms. In a lower subdivision of the Cutch Jurassic rocks, the Katrol group, shown by numerous Ammonites to be allied to Kimmeridge and upper Oxford beds of Western Europe, four species of plants have been found, of which three are met with in the Umia beds, and the fourth, an English Oolitic form, in the Jabalpur series. This evidence seems in favour of the view that the flora underwent change more slowly than the marine fauna.

It will be as well, before leaving the subject of the Gondwána groups, to show in a tabular form the geological age assigned to the flora and fauna of each separately, on the evidence afforded

[1] *Q. J. G. S.* 1869, pp. 138, 152, &c.; 1875, p. 427; *Pal. Ind.* ser. iv. pt. 1; *Man. Geol. Ind.* p. 151.

by comparison with the plants and animals known from European formations.

		Plants	Animals
Upper Gondwána	Cutch	Middle Jurassic	Uppermost Jurassic ? Neocomian (marine)

Lower Gondwána	Panchet	Rhætic	Triassic or Permian
	Damuda	Middle Jurassic	Middle Jurassic
	Karharbári, Talchir	Lower Triassic	—

Flora of Tonquin.—Quite recently M. Zeiller has described a series of plants from some coal-bearing beds in Tonquin (*Bull. Soc. Géol.* ser. iii. vol. xi. p. 456). This flora is very extraordinary in every respect. It consists of twenty-two species, and contains only two peculiar forms; ten, or nearly one-half, are European species found in the Lower Lias or Rhætic; whilst of the remaining ten, five are Damuda forms *Noeggerathiopsis hislopi, Macrotæniopteris feddeni, Palæovittaria kurzi, Glossopteris browniana,* and *Phyllotheca indica,* one species being common to the Newcastle beds and Carboniferous flora of Australia, and two others closely allied to the forms there occurring. The other five are said to be Rájmahál forms, four *Tæniopteris* or *Angiopteridium* and an *Otozamites.* M. Zeiller unhesitatingly classes the Tonquin beds as Rhætic. It is most singular that these coal-beds, although more distant from Europe by 18° of longitude than either the Damuda or Rájmahál beds of India, contain a larger proportion of European fossil species than any known Indian plant-beds; whilst the association in the same strata of upper and lower Gondwána forms, if well ascertained, shows how hopeless is the attempt to classify these deposits by plant evidence alone.

Australian Coal-Measures and Associated Beds.—In the notice of the lower Gondwána floras of India it was observed that there was a great resemblance between some of them and those found in certain beds of Australia. These latter present even a more remarkable instance of homotaxial perversity than do the Indian rocks. The Australian plant-bearing beds are found in Eastern and Southern Australia, Queensland, and Tasmania. For a knowledge of the geology of the country we are chiefly indebted to the writings of the late Mr. Clarke,[1] whilst the flora has been worked out by McCoy, Dana, Carruthers, and Feistmantel, the latter having recently published a much more complete account than was previously available (*Palæontographica.—Pal. u. mes. Flora des östl. Australien,* 1878-79).

The following are the fresh-water or subaerial beds of Australia, according to the latest classification:—

6. Clarence River beds, New South Wales (Mesozoic carbonaceous of Queensland, Victoria, and Tasmania).
5. Wianamatta beds, N.S. Wales.
4. Hawkesbury beds, N. S. Wales (Bacchus Marsh sandstones, Victoria).
3. Newcastle beds, N.S. Wales.
2. Lower Coal-Measures with marine layers interstratified, N.S. Wales.
1. Lower Carboniferous beds, N.S. Wales.

To a still lower horizon probably belong some beds in Queensland, containing *Lepidodendron nothum* and *Cyclostigma.* They are considered Devonian by Carruthers, and there are some ancient plant-beds in Victoria that may be of the same period.

1. *Lower Carboniferous Beds.*—These underlie the beds with a Carboniferous marine fauna. The localities given are Smith's Creek, near Stroud, Port Stephens, and Arowa. The following plants are enumerated:—

LYCOPODIACEÆ.—*Cyclostigma,* 1 sp.; *Lepidodendron,* 2 or 3; *Knorria,* 1.
FILICES.—*Rhacopteris,* 4; *Archæopteris,* 2 (?); *Glossopteris,* 1.
EQUISETACEÆ.—*Calamites,* 2; *Sphenophyllum,* 1.

This flora contains several species identical with those in the Lower Carboniferous (Bernician) of Europe, corresponding to the mountain limestone. The agreement both in homotaxis and position is the more remarkable because of the startling contrast in the next stage. The only peculiarity is the presence of a *Glossopteris.* This comes from a different locality—Arowa—from most of the fossils, and the species is identical with one found in a much higher series. Under these circumstances it is impossible to feel satisfied that the specimen was really from this horizon. The evidence is not so clear as is desirable.

2. *Lower Coal Measures with Marine Beds.*—The following plants are recorded:—

CYCADEACEÆ.—*Noeggerathiopsis,* 1 sp.
FILICES.—*Glossopteris,* 4.
EQUISETACEÆ.—*Annularia,* 1; *Phyllotheca,* 1.

In the marine beds, which are interstratified, are found Lower Carboniferous (mountain limestone) marine fossils in abundance, such as *Orthoceras, Spirifer, Fenestella, Conularia,* &c. The plants belong to forms declared to be typically Jurassic by palæontologists. As the interstratification of the marine and plant-bearing beds has been repeatedly questioned by palæontologists, it is necessary to point out that the geological evidence brought forward by Mr. Clarke is of the clearest and most convincing character, that this evidence has been confirmed by all the geologists who are acquainted with the country, and has only been doubted by those who have never been near the place.

3. *Newcastle Beds.*—By all previous observers in the field these had been united to the preceding and the flora declared to be the same. Dr. Feistmantel has, however, pointed out important differences. Unfortunately, as he has been unable to examine the beds, it still remains uncertain whether the distinction, which has been overlooked by all the field geologists, is quite so great as it appears from the list of fossils given. The following is the flora:—

CONIFERÆ.—*Brachyphyllum,* 1 sp.
CYCADEACEÆ.—*Zeugophyllites,* 1; *Noeggerathiopsis,* 3.
FILICES.—*Sphenopteris,* 4; *Glossopteris,* 8; *Gangamopteris,* 2; *Caulopteris* (?), 1.
EQUISETACEÆ.—*Phyllotheca,* 1; *Vertebraria,* 1.

The only animal known from the beds is a heterocercal ganoid fish, *Urosthenes australis,* a form with Upper Palæozoic affinities.

It will be noticed that the difference from the flora of the underlying beds associated with marine strata is chiefly specific, and by no means indicative of great difference of age, though the only species considered as common to the two by Dr. Feistmantel is *Glossopteris browniana,* found also in the Damuda series of India, in Tonquin, and in South Africa.

The plant fossils of the Newcastle beds and of the underlying series with marine fossils are those which exhibit so remarkable a similarity to the flora of the Indian lower Gondwánas, and especially to the Damudas. The same genera of plants, especially *Noeggerathiopsis, Glossopteris, Phyllotheca, Vertebraria,* prevail in both. But the lower beds of Australia, to judge by the marine fauna, are of Lower Carboniferous age, and it is impossible to suppose that the Newcastle beds are of very much later date. They are said to be conformable to the lower beds with marine fossils, and even to pass into them, and they should probably, if the lower beds are Lower Carboniferous, be classed as Middle or Upper Carboniferous. Thus if the evidence of marine faunas be accepted as decisive, the Damuda beds of India are homotaxially related to Jurassic strata in Europe and to Carboniferous in Australia.

But the Australian Newcastle flora has been quite as positively classed as Jurassic by European palæobotanists as that of the Damudas. It would be easy to quote a long list of authorities—McCoy, De Zigno, Saporta, Schimper, Carruthers, and others—in support of the Jurassic age of the Australian beds. For years the testimony of Australian geologists was rejected, and doubts thrown upon their observations. There is, so far as I know, no case in the whole history of palæontology in which the conflict of palæontological evidence has been so remarkably displayed.

4. *Hawkesbury Beds.*—The fauna and flora are poor. Only two fish, *Clithrolepis granulatus* and *Myriolepis clarkei,* and one plant, *Thinnfeldia odontopteroides,* are known, and of the three forms two recur in the Wianamatta beds.

An important character of the Hawkesbury beds, to which further reference will be made presently, is the occurrence of transported boulders (Wilkinson, quoted by Feistmantel, *Rec. Geol. Surv. Ind.* 1880, p. 257), apparently brought thither by the action of ice.

Similar boulders have been observed in certain sandstones in

[1] *Q. J. G. S.* 1861, p. 354, and *Remarks on the Sedimentary Formations of New South Wales,* 1878, besides numerous other works.

Victoria known as the Bacchus Marsh beds. From these beds species of *Gangamopteris* have been described by McCoy. *Gangamopteris*, it should be recollected, is a genus of ferns closely allied to *Glossopteris*, and abundant in the Damuda and still more so in the Karharbári beds of the lower Gondwánas in India.

5. *Wianamatta Beds.*—These are the highest portion of the whole system in New South Wales. They contain the following organic remains:—

ANIMALS.

PISCES.—*Palæoniscus antipodeus*, *Clithrolepis granulatus*.

PLANTS.

FILICES.—*Thinnfeldia* (*Pecopteris*) *odontopteroides*, *Odontopteris microphylla*, *Pecopteris tenuifolia*, *Tæniopteris wianamattæ*.

EQUISETACEÆ.—*Phyllotheca hookeri*.

The fish from the Wianamatta, Hawkesbury, and Newcastle beds, four in number, were considered as a whole by Sir P. Egerton to be most nearly allied to the Permian fauna of Europe.

The Wianamatta plants, like those in the lower beds, are classed as Jurassic.

6. *Higher Mesozoic Beds.*—These, which do not appear to have been traced into connection with the Wianamatta and Hawkesbury beds, occur in widely separated localities, from Queensland to Tasmania. The correlation of these widely scattered deposits, and the assignment of them collectively to a position above that of the Wianamatta beds, appear solely founded upon the fossil flora, and it would be satisfactory to have in addition some geological evidence or some palæontological data derived from marine fossils. The Queensland flora is said to occur in beds overlying marine strata of Middle Jurassic age.

The following plants are recorded from these higher beds:—

CYCADEACEÆ. *Zamites* (*Podozamites*), 3 sp.; *Otozamites*, 1.
FILICES. *Sphenopteris*, 1; *Thinnfeldia*, 1; *Cyclopteris*, 1; *Alethopteris*, 1; *Tæniopteris*, 1; *Sagenopteris*, 1.
EQUISETACEÆ.—*Phyllotheca*, 1.

Tabulating, as in the case of the Indian Gondwána system, the age of the different Australian subdivisions as determined by their fossil plants and animals on purely palæontological grounds, we have the following result:—

	Plants	Animals
6. Higher Mesozoic beds	Jurassic	Jurassic (marine)
5. Wianamatta beds	Jurassic	Permian
4. Hawkesbury beds	Jurassic	Permian
3. Newcastle beds	Jurassic	Permian
2. Lower Coal-Measures	Jurassic	Lower Carboniferous (marine)
1. Lower Carboniferous beds	Lower Carboniferous	—

South Africa.—In connection with the later Palæozoic and older Mesozoic rocks of Australia and India, it is of importance to mention briefly the corresponding fresh-water or subaerial formations of Southern Africa, although in that country there are not such marked discrepancies in the palæontological evidence, perhaps because the relations of the beds with remains of animals to the plant-bearing strata are less clearly known. It will be sufficient to notice some of the most prominent peculiarities of these formations here, as I hope that a fuller account will be given to the section by Prof. Rupert Jones, who has made an especial study of South African geology.

In the interior of South Africa, occupying an immense tract in the northern parts of Cape Colony, the Orange Free State, Transvaal, and the deserts to the westward of the last two, there is a great system of sandstone and shales with some coal-beds generally known as the Karoo formation. The sequence of subdivisions is the following (*Q. J. G. S.* xxiii. 1867, p. 142):—

Stormberg beds,	about	1800 feet thick
Beaufort	,, ,,	1700 ,, ,,
Koonap	,, ,,	1500 ,, ,,

The beds are but little disturbed in general, and form great plateaux. They rest partly on Palæozoic rocks (Carboniferous or Devonian), partly on gneissic formations. As in Australia, the underlying Palæozoic rocks contain a flora allied to the Carboniferous flora of Europe.

At the base of the Karoo formation are certain shales with coal, known as the Ecca beds, and remarkable for containing a great boulder-bed, the Ecca or Dwyka conglomerate (Sutherland, *Q. J. G. S.* xxvi. p. 514), like that in the Tálchir beds in India and the Hawkesbury sandstone in Australia, the boulders, precisely as in the Tálchir beds, being embedded in fine compact silt or sandstone, which in both countries has been mistaken for a volcanic rock. The Ecca beds are said to contain *Glossopteris* and some other plants, but the accounts are as yet somewhat imperfect. The whole Karoo system, according to the latest accounts, rests unconformably on the Ecca beds, whilst the Ecca beds are conformable to the underlying Palæozoic strata.

Unfortunately, although a considerable number of animals and a few plants have been described from the "Karoo formation," it is but rarely that the precise subdivision from which the remains were brought has been clearly known.

The known species of plants are very few in number: *Glossopteris browniana*, and two other species of *Glossopteris* (one classed by Tate as *Dictyopteris*, (*Q. J. G. S.* xxiii. p. 141) *Rubidgea*, a fern nearly akin to *Gangamopteris* and *Glossopteris*, and a *Phyllotheca*-like stem are recorded, without any certain horizon, but probably from the Beaufort beds. There is no doubt as to the close similarity of these plants to those of the Damudas of India and the Newcastle beds of Australia.

From the Stormberg beds there are reported *Pecopteris* or *Thinnfeldia odontopteroides*, *Cyclopteris cuneata*, and *Tæniopteris daintreei* (Dunn, "Report on Stormberg Coal-Field," *Geol. Mag.* 1870, p. 552), three of the most characteristic fossils of the uppermost plant-beds in Australia, and all found in the upper Jurassic Queensland beds.

The animals found in the Karoo beds (Owen, "Cat. Foss. Rept. S. Africa, Brit. Mus. 1876," &c.) are more numerous by far than the plants. The greater portion have been secured from the Beaufort beds. They comprise numerous genera of dicynodont, theriodont, and dinosaurian reptiles, two or three genera of labyrinthodont amphibians, some fish allied to *Palæoniscus* and *Amblypterus*, and one mammal, *Tritylodon*. Of the above the *Tritylodon* and some reptilian and fish remains are said to be from the Stormberg beds.

Tritylodon is most nearly related to a Rhætic European mammal. The relations of the reptiles called *Theriodontia* by Sir R. Owen are not clearly defined, but representatives of them and of the *Dicynodontia* as already noticed are said to be found in the Permian of Russia. The *Glossopteris* and its associates may of course be classed as Carboniferous or Jurassic, according to taste. Neither the fauna nor flora show sufficiently close relations to those of any European beds for any safe conclusions as to age, even if homotaxis and synchronism be considered identical. On the other hand, there are remarkable points of agreement with the faunas and floras of the Indian and Australian rocks.

Away from the typical Karoo area on the coast south of Natal there is found a series of beds, partly marine, sometimes called the Uitenhage (*Q. J. G. S.* xxvii. p. 144) series. A few cycads (*Otozamites*, *Podozamites*, *Pterophyllum*), a conifer, and ferns (*Pecopteris* or *Alethopteris*, *Sphenopteris*, *Cyclopteris*) are quoted from them, and three or four of the forms are closely allied identical with species found in the Rájmahál beds of India.

It was at first supposed that the plant-bearing beds were lower in position than those containing marine fossils, and the whole of the Uitenhage series was considered as of later age than the Karoo beds. The marine beds were considered Middle Jurassic. Subsequently, however, Stow (*Q. J. G. S.* xxvii. p. 479) showed conclusively that a portion of the marine beds, judging by their fossils, are of uppermost Jurassic or even Neocomian age, and also that the relation of the plant-bearing beds to the marine strata are far less simple than was supposed (*l.c.* p. 505, 511, 513, &c.). Indeed, to judge from Stow's account, it is by no means clear that a portion of the wood-bed series or saliferous series, to which the plant-beds belong, is not higher in position than the marine Jurassic strata.

There is a very extraordinary similarity between the geology of the southern part of Africa and that of the peninsula of India. In both countries a thick fresh-water formation, without any marine beds intercalated, occupies a large area of the interior of the country, whilst on the coast some marine Jurassic and Cretaceous rocks are found, the former in association with beds containing plants. The coincidence is not even confined to sedimentary beds. As in India so in South Africa, the uppermost inland Mesozoic fresh-water beds are capped by volcanic rocks.

It has been assumed, but not apparently on any clear evidence,

that the marine coast-beds and the associated plant-beds are in Africa much newer than the inland sandstone formation, but it is not impossible that the relations may really be the same as in India, and that the Stormberg beds of the inland formation may be the equivalents of the Upper Jurassic or even the Cretaceous marine beds on the coast. The discovery of plants identical with those of the Jurassic (probably Upper Jurassic) beds of Queensland in the Stormberg series may of course be taken for what it is worth; it is of quite as much importance in indicating the age of the rocks as the occurrence of dicynodont reptiles in the Permian of Russia and in the lower Godwánas of India.

Altogether there is quite sufficient probability that the upper Karoo or Stormberg beds are of later age than Triassic to justify the protest which I made last year against a skull being described from these beds as that of a "Triassic" mammal (*Q. J. G. S.* xl. p. 146). The practice, so common amongst palæontologists, of positively asserting as a known fact the geological age of organisms from beds of which the geological position is not clearly determined is very much to be deprecated.

I have called attention to the occurrence of boulders in the Tálchir beds in India, the Ecca beds of South Africa, and the Bacchus Marsh sandstones and Hawkesbury beds of Australia. The idea has occurred quite independently to several different observers that each of these remarkable formations affords evidence of glacial action; and although, in the case of India especially, the geographical position of the boulder-bed within the tropics seemed for a long time to render the notion of ice action too improbable to be accepted, further evidence has so far confirmed the view as to cause it to be generally received. Even before the Australian boulder-deposits had been observed, it was suggested that the Tálchir beds and Ecca conglomerate might be contemporaneous (*Q. J. G. S.* xxxi. p. 528), and that the evidence in favour of a Glacial epoch having left its traces in the Permian beds of England (*Q. J. G. S.* xi. p. 185) might possibly indicate that the Indian and South African boulder-beds are of the same geological epoch. The discovery of two similar deposits in Australia adds to the probability that all may have resulted from the same cause and may record contemporaneous phenomena. It would be very unwise to insist too much on the coincidence.

It would be easy to call attention to further examples of discrepancies in palæontological evidence, but I should weary you and nothing would be attained by going through instance after instance of deposits in distant parts of the world, the age of which has been solely determined by the examination of a few fossil forms of land and fresh-water animals and plants. I have, therefore, only taken a few with the details of which I have had occasion to become acquainted. In some of the most important cases I have mentioned, such as those of the Pikermi and Siwalik faunas, the Cutch (Umia beds) flora, and that in the lower Coal-Measures of Australia, the conflict is between the evidence of the marine and terrestrial organisms. Manifestly one or the other of these leads to erroneous conclusions.

The general opinion of geologists is in favour of accepting the evidence of marine organisms. The reason is not far to seek. So far as I am aware no case is known where such an anomaly as that displayed in the Gondwánas of India has been detected amongst marine formations of which the sequence was unquestioned. In the Gondwánas we have a Rhætic flora overlying a Jurassic flora, and a Triassic fauna above both. In Australia we find a Jurassic flora associated with a Carboniferous marine fauna, and overlaid by a Permian fresh-water fauna. The only similar case amongst marine strata is that of the well-known colonies of the late M. Barrande in Bohemia, and in this instance the intercalation of strata containing later forms amongst beds with older types is disputed, whilst the difference in age between the faunas represented is not to be compared to that between Triassic and Jurassic.

There is, however, another and an even stronger reason for accepting the evidence of marine instead of that afforded by terrestrial and fresh-water animals and plants. If we compare the distribution of the two at the present day, we shall find a very striking difference, and it is possible that this difference may afford a clue to the conditions that prevailed in past times.

Wanderers into what they fancy unexplored tracts in palæontology are very likely to find Prof. Huxley's footprints on the path they are following. I have had occasion to turn to a paper of his on *Hyperodapedon* (*Q. J. G. S.* xxv. p. 150), that very curious reptile already mentioned, of which the remains occur both in Great Britain and in India, and I find the following remarks, which appear so exactly to express a portion of the view to which I wish to call your attention, that I trust I may be excused for quoting them. Prof. Huxley writes:—

"It does not appear to me that there is any necessary relation between the fauna of a given land and that of the seas of its shores. The land-faunæ of Britain and Japan are wonderfully similar; their marine faunæ are in several ways different. Identical marine shells are collected on the Mozambique coast and in the easternmost islands of the Pacific; whilst the faunæ of the lands which lie within the same range of longitude are extraordinarily different. What now happens geographically to provinces in space is good evidence as to what, in former times, may have happened to provinces in time; and an essentially identical land-fauna may have been contemporary with several successive marine faunæ.

"At present our knowledge of the terrestrial faunæ of past epochs is so slight that no practical difficulty arises from using, as we do, sea-reckoning for land-time. But I think it highly probable that sooner or later the inhabitants of the land will be found to have a history of their own."

When these words were written more than twenty-four years ago, scarcely one of the geological details to which I have called your attention was known. I need not point out how wonderful a commentary such details have afforded to Prof. Huxley's views.

I have no desire to quote authority. I fear that in the facts I have been laying before you my quotations of the most authoritative writers have been made less for the purpose of showing reverence than of expressing scepticism. My reason for calling attention to Prof. Huxley's views is different. I entirely agree with them; but there is, I think, something to be added to them. There is, I believe, an additional distinction between land and marine faunas that requires notice, and this distinction is one of very great importance and interest. It appears to me that at the present day the difference between the land-faunas of different parts of the world is so vastly greater than that between the marine faunas that, if both were found fossilised, whilst there would be but little difficulty in recognising different marine deposits as of like age from their organic remains, terrestrial and fresh-water beds would in all probability be referred to widely differing epochs, and that some would be more probably classed with those of a past period than with others of the present time.

I had proposed to enter at some length into this subject, and to attempt a sketch of the present state of our knowledge concerning the distribution of terrestrial and marine faunas and floras. But I found that it was impossible to do justice to the question without making this address far longer than is desirable, and I have already taken up more time than I ought to have done. I can therefore only treat the subjects very briefly.

As you are doubtless aware, the most important work upon the distribution of terrestrial animals yet published is that of Mr. Wallace. He divides the earth's surface into six regions—Palæarctic, Ethiopian, Oriental, Australian, Neotropical, and Nearctic. Some naturalists, with whom I am disposed to agree, consider Madagascar and the adjacent islands a seventh region, and it is possible that one or two other additions might be made.

These regions are essentially founded on the distribution of *Vertebrata*, especially mammals and birds, and the following table, taken from Wallace's lists, shows the percentage of peculiar families of Vertebrata and peculiar genera of Mammalia in each region, Mammalia being selected as being more characteristic than birds, and better known than reptiles, amphibians, or fishes:—

Regions	Total Families of Vertebrates	liar lies	of Peculi Familie	Total Genera Mamma	Peculia Genera Mammal	
PALÆARCTIC	137	3	2 2	100	37	37
ETHIOPIAN	175	23	13·1	142	90	63
ORIENTAL	163	12	7·4	118	54	46
AUSTRALIAN	142	30	21·1	70	45	65
NEOTROPICAL	168	45	26 8	131	103	79
NEARCTIC	121	12	9 9	74	24	32

The marine mammals and reptiles are too few in number to

be compared with the land-fauna, but whales, porpoises, seals, sirenians, turtles, and sea-snakes are for the most part widely diffused. The best class of the Vertebrata for comparison is that of the fishes, and some details taken by Wallace from Günther's "British Museum Catalogue" are very important. The whole class is divided into 116 families, of which 29 are exclusively confined to fresh water, whilst 80 are typically marine. Of these 80 no less than 50 are universally, or almost universally, distributed, whilst many others have a very wide range. Four families are confined to the Atlantic and 13 to the Pacific Ocean, whilst a few more are exclusively southern or northern. About 63 are found in both the Atlantic and Pacific.

Now, of the 29 fresh-water families, 15, or more than one-half, are confined each to a single region, 9 are found each in two regions, 2 in three regions, and the same number in four; one only (*Cyprinidæ*) is found in five regions, whilst not one is met with in all six. It is impossible to conceive a greater contrast: 50 marine families, or 62·5 per cent., have a world-wide distribution, whilst not a single fresh-water family has an equally extended range, and more than one-half are confined each to a single region.

The regions adopted by Wallace, as already stated, are founded on the *Vertebrata*; he considers, however, that the distribution of the invertebrates is similar. So far as the terrestrial Mollusca are concerned, I am inclined to dissent from this view. But for one circumstance, the Mollusca would afford an admirable test of the theory that marine types—species, genera, and families—are much more widely spread than terrestrial. I am assured that this is the case, but the difficulty of proving it arises from the fact that the classification of pulmonate terrestrial Mollusca, as adopted by naturalists generally, is so artificial as to be worthless. Genera like *Helix*, *Bulimus*, *Achatina*, *Pupa*, *Vitrina*, as usually adopted, are not real genera, but associations of species united by characters of no systematic importance, and the attempts that have hitherto been made at a natural classification have chiefly been founded on the shells, the animals not being sufficiently known for their affinities, in a very large number of cases, to be accurately determined. Of late years, however, more attention has been devoted to the soft parts of land mollusks, and in Dr. Paul Fischer's "Manuel de Conchyliologie" now being published, classification of the Pulmonate Gasteropoda is given, which, although still imperfect for want of additional information, is a great improvement upon any previously available. In this work the first 13 families of the *Pulmonata Geophila* comprise all the non-operculate land Mollusca, or snails and slugs, and these 13 families contain 82 genera thus distributed:—

Peculiar to one of Wallace's land regions . . .	54
Found in more than one, but not in both Americ and the Eastern Hemisphere.	
Common to both hemispheres	16

The last 16, however, include *Limax*, *Vitrina*, *Helix*, *Pupa*, *Vertigo*, and some other genera which certainly need further repartition. The operculated land-shells belonging to a distinct sub-order, or order, and closely allied to the ordinary Prosobranchiate Gasteropoda, are better classified, the shells in their case affording good characters. They comprise four well-marked families (*Helicinidæ*, *Cyclostomidæ*, *Cyclophoridæ*, and *Diplommatinidæ*), besides others less well marked or but doubtfully terrestrial. Not one of the families named is generally distributed, and the genera are for the most part restricted to one or two regions. The portion of Dr. Fischer's manual relating to these Mollusca is unpublished, and the latest general account available is that of Pfeiffer, published in 1876 (*Monographia Pnemonoponorum Viventium, Supp.* iii.). From this monograph I take the following details of distribution. The number of genera enumerated is 64 (including *Proserpinidæ*).

Peculiar to one of Wallace's land regions . . .	48
Found in more than one, but not in both America and the Eastern Hemisphere	8
Common to both hemispheres	8

It is the distribution of the terrestrial operculate Mollusca which induces me to suspect that the distribution of land Mollusca differs from that of land vertebrates. One instance I may give. There is nowhere a better-marked limit to two vertebrate faunas than that known as Wallace's line separating the Australian and Oriental regions, and running through the Malay peninsula between Java, Sumatra, and Borneo on the one hand, and Papua with the neighbouring groups on the other. There is in the two regions a very great difference in the vertebrate genera, and a considerable replacement of families. The Oriental *Vertebrata* contain far more genera and families common to Africa than to Australia. Now, the operculate land-shells known from New Guinea and Northern Australia belong to such genera as *Cyclophorus*, *Cyclotus*, *Leptopoma*, *Pupinella*, *Pupina*, *Diplommatina*, and *Helicina*, all found in the Oriental region, and mostly characteristic of it, whilst the only peculiar types known are *Leucoptychia*, closely allied to *Leptopoma*, from New Guinea, and *Heterocyclus*, apparently related to the Indian *Cyathopoma*, from New Caledonia. Farther east, in Polynesia, there are some very remarkable and peculiar types of land-shells, such as *Achatinella*, but these do not extend to Australia or Papua. On the other hand, scarcely a single Oriental genus extends to Africa, the terrestrial molluscan fauna of which continent differs far more from that of the Oriental region than the latter does from that of tropical Australia.

The same is the case with plants. In an important work lately published by Dr. O. Drude of Dresden, the tropics of the Old World are divided into three distinct regions—(1) tropical Africa; (2) the East African islands, Madagascar, &c.; (3) India, South-Eastern Asia, the Malay Archipelago, Northern Australia, and Polynesia.

A very large proportion of the families and even of the genera of marine Mollusca are almost of world-wide distribution, and even of the tropical and sub-tropical genera the majority are found in all the warmer seas. I have no recent details for the whole of the marine Mollusca, but a very fair comparison with the data already given for land-shells may be obtained from the first twenty-five families of Prosobranchiate Gasteropoda, all that are hitherto published in Fischer's manual. These twenty-five families include *Conidæ*, *Olividæ*, *Volutidæ*, *Buccinidæ*, *Muricidæ*, *Cypræidæ*, *Strombidæ*, *Cerithiidæ*, *Planaxidæ*, and their allies, and contain 116 living marine genera, the known range of which is the following:—

Found only in the Atlantic Ocean	15	
Found only in the Pacific or Indian Ocean, or both	28	
Found only in Arctic or Antarctic Seas, or in both	12	
		55
Found in the warmer parts of all oceans . . .	34	
Widely, and for the most part universally, distributed	27	
		61

That is, 52·6 per cent. are found in both hemispheres, whilst only 19·5 per cent. of the inoperculate, and 12·5 per cent. of the operculate land Mollusca, have a similar distribution. This is, however, only an imperfect test of the difference, which is really much greater than these numbers named imply by themselves.

Some genera of fresh-water Mollusca, as *Unio*, *Anodon*, *Cyclas*, *Lymnea*, *Planorbis*, *Paludina*, and *Bythinia*, are very widely spread, but a much larger number are restricted. Thus, if *Unio* and *Anodon* are extensively distributed, all allied fresh-water genera, like *Monocondylæa*, *Mycetopus*, *Iridina*, *Spatha*, *Castalia*, *Ætheria*, and *Mülleria*, inhabit one or two regions at the most. The same result is not found from taking an equally important group of marine Mollusca, such as *Veneridæ* or *Cardiadæ*.

Throughout the marine Invertebrata, so far as I know, the same rule holds good: a few generic types are restricted to particular seas; the majority are found in suitable habitats throughout a large portion of the globe. The marine provinces that have been hitherto distinguished, as may be seen by referring to those in Woodward's "Manual of the Mollusca," or Forbes and Godwin-Austen's "Natural History of the European Seas," or Fischer's "Manuel de Conchyliologie," or Agassiz' "Revision of the Echini," are founded on specific distinctions, whilst the terrestrial regions are based on generic differences, and often on the presence or absence of even larger groups than genera.

Botany offers a still more remarkable example. I have just referred to Dr. Oscar Drude's work (*Petermann's Mittheilungen*, Ergänzungsheft, No. 74, "Die Florenreiche der Erde"), published within the last few months, on the distribution of plants. Dr. Drude divides the surface of the globe into four groups of floral regions (*Florenreichsgruppe*), and these again into floral regions (*Florenreiche*), fifteen in number, which are again divided into sub-regions (*Gebiete*). The first group of floral regions is the oceanic, comprising all the marine vegetation of the world;

and so uniform is this throughout that no separate regions can be established, so that there is but one oceanic to contrast with fourteen terrestrial regions.

It is impossible to enter further into this subject now, and I can only allude to the evidence in favour of the existence of land-regions in past times. It is scarcely necessary to remind you of the proofs already accumulated of differences between the fauna of distant countries in Tertiary times. The Eocene, Miocene, and Pliocene Vertebrata of North America differ quite as much from those of Europe in the same periods as do the genera of the present day; and there was as much distinction between the Mammalia of the Himalayas and of Greece when the Siwalik and Pikermi faunas were living as there is now. In Mesozoic times we have similar evidence. The reptiles of the American Jurassic deposits present wide differences from those of the European beds of that age, and the South African reptilian types of the Karoo beds are barely represented elsewhere. But there is no reason for supposing that the limits or relations of the zoological and botanical regions in past times were the same as they now are. It is quite certain indeed that the distribution of land-areas, whether the great oceanic tract has remained unchanged in its general outlines or not, has undergone enormous variations, and the migration of the terrestrial fauna and flora must have been dependent upon the presence or absence of land communication between different continental tracts; in other words, the terrestrial regions of past epochs, although just as clearly marked as those of the present day, were very differently distributed. The remarkable resemblance of the floras in the Karoo beds of South Africa, the Damuda of India, and the Coal-Measures of Australia, and the wide difference of all from any European fossil flora, is a good example of the former distribution of life; whilst it is scarcely necessary to observe that the present Neotropical and Australian mammals resemble those of the same countries in the later Tertiary times much more than they do the living Mammalia of other regions, and that the Australian mammal fauna is in all probability more nearly allied to the forms of life inhabiting Europe in the Mesozoic era than to any European types of later date. If the existing mammals of Australia had all become extinct, a deposit containing their bones would probably have been classed as Mesozoic.

The belief in the former universality of faunas and floras is very much connected with the idea once generally prevalent, and still far from obsolete, that the temperature of the earth's surface was formerly uniform, and that at all events until early or even Middle Tertiary times the Poles were as warm as the Equator, and both enjoyed a constant tropical climate. The want of glacial evidence from past times in Spitzbergen and Greenland, where a temperature capable of supporting arboreal vegetation has certainly prevailed during several geological periods, is counterbalanced by the gradually accumulating proofs of Lower Mesozoic or Upper Palæozoic Glacial epochs in South Africa, Australia, and, strangest of all, in India. Even during those periods of the earth's history where there is reason to believe that the temperature in high latitudes was higher than it now is, evidence of distinct zones of climate has been observed, and quite recently Dr. Neumayr,[1] of Vienna, has shown that the distribution of Cretaceous and Jurassic *Cephalopoda* throughout the earth's surface proves that during those periods the warmer and cooler zones of the world existed in the same manner as at present, and that they affected the distribution of marine life as they do now.

The idea that marine and terrestrial faunas and floras were similar throughout the world's surface in past times is so ingrained in palæontological science that it will require many years yet before the fallacy of the assumption is generally admitted. No circumstance has contributed more widely to the belief than the supposed universal diffusion of the Carboniferous flora. The evidence that the plants which prevailed in the Coal-Measures of Europe were replaced by totally different forms in Australia, despite the closest similarity in the marine inhabitants of the two areas at the period, will probably go far to give the death-blow to an hypothesis that rests upon no solid ground of observation. In a vast number of instances it has been assumed that similarity between fossil terrestrial faunas and floras proves identity of geological age, and, by arguing in a vicious circle, the occurrence of similar types assumed without sufficient proof to belong to the same geological period has been alleged as evidence of the existence of similar forms in distant countries at the same time.

In the preceding remarks it may perhaps have surprised some of my auditory that I have scarcely alluded to any American formations, and especially that I have not mentioned so well-known and interesting a case of conflicting palæontological evidence as that of the Laramie group. My reason is simply that there are probably many here who are personally acquainted with the geology of the American Cretaceous and Tertiary beds, and who are far better able to judge than I am of the evidence as a whole. To all who are studying such questions in America I think it will be more useful to give the details of similar geological puzzles from the Eastern Hemisphere than to attempt an imperfect analysis of difficult problems in the great Western continent.

Perhaps it may be useful, considering the length to which this address has extended, to recapitulate the principal facts I have endeavoured to bring before you. These are—

1. That the geological age assigned on homotaxial grounds to the Pikermi and Siwalik mammalian faunas is inconsistent with the evidence afforded by the associated marine deposits.

2. The age similarly assigned on the same data to the different series of the Gondwána system of India is a mass of contradictions: beds with a Triassic fauna overlying others with Rhætic or Jurassic floras.

3. The geological position assigned on similar evidence to certain Australian beds is equally contradictory, a Jurassic flora being of the same age as a Carboniferous marine fauna.

4. The same is probably the case with the terrestrial and fresh-water faunas and floras of South Africa.

5. In instances of conflicting evidence between terrestrial or fresh-water faunas and floras on one side, and marine faunas on the other, the geological age indicated by the latter is probably correct, because the contradictions which prevail between the evidence afforded by successive terrestrial and fresh-water beds are unknown in marine deposits, because the succession of terrestrial animals and plants in time has been different from the succession of marine life, and because in all past times the differences between the faunas and floras of distant lands have probably been, as they now are, vastly greater than the differences between the animals and plants inhabiting the different seas and oceans.

6. The geological age attributed to fossil terrestrial faunas and floras in distant countries on account of the relations of such faunas and floras to those found in European beds has proved erroneous in so large a number of cases that no similar determinations should be accepted unless accompanied by evidence from marine beds. It is probable in many cases—perhaps in the majority—where the age of beds has been determined solely by the comparison of land or fresh-water animals or plants with those found in distant parts of the globe, that such determinations are incorrect.

SECTION II

ANTHROPOLOGY

Opening Address by Edward B. Tylor, D.C.L., F.R.S., President of the Section

Our newly-constituted Section of Anthropology, now promoted from the lower rank of a Department of Biology, holds its first meeting under remarkable circumstances. Here in America one of the great problems of race and civilisation comes into closer view than in Europe. In England anthropologists infer from stone arrow-heads and hatchet-blades, laid up in burial-mounds or scattered over the sites of vanished villages, that Stone Age tribes once dwelt in the land; but what they were like in feature and complexion, what languages they spoke, what social laws and religion they lived under, are questions where speculation has but little guidance from fact. It is very different when under our feet in Montreal are found relics of a people who formerly dwelt here. Stone Age people, as their implements show, though not unskilled in barbaric arts, as is seen by the ornamentation of their earthen pots and tobacco-pipes, made familiar by the publications of Principal Dawson. As we all know, the record of Jacques Cartier, published in the sixteenth century collection of Ramusio, proves by text and drawing that here stood the famous palisaded town of Hochelaga. Its inhabitants, as his vocabulary shows, belonged to the group of tribes whose word for 5 is *wisk*—that is to say, they were of

[1] "Ueber klimatische Zonen während der Juras und Kreidezeit," *Denkschr. Math. Nat. Cl. Akad. Wiss. Wien*, vol. xlvii. 1883.

the Iroquois stock. Much as Canada has changed since then, we can still study among the settled Iroquois the type of a race lately in the Stone Age, still trace remnants and records of their peculiar social institutions, and still hear spoken their language of strange vocabulary and unfamiliar structure. Peculiar importance is given to Canadian anthropology by the presence of such local American types of man, representatives of a stage of culture long passed away in Europe. Nor does this by any means oust from the Canadian mind the interest of the ordinary problems of European anthropology. The complex succession of races which make up the pedigree of the modern Englishman and Frenchman, where the descendants perhaps of palæolithic, and certainly of neolithic, man have blended with invading Keltic, Roman, Teutonic-Scandinavian peoples—all this is the inheritance of settlers in America as much as of their kinsfolk who have stayed in Europe. In the present scientific visit of the Old to the New World, I propose to touch on some prominent questions of anthropology with special reference to their American aspects. Inasmuch as in an introductory address the practice of the Association tends to make arguments unanswerable, it will be desirable for me to suggest rather than dogmatise, leaving the detailed treatment of the topics raised to come in the more specialised papers and discussions which form the current business of the Section.

The term *prehistoric*, invaluable to anthropologists since Prof. Daniel Wilson introduced it more than thirty years ago, stretches back from times just outside the range of written history into the remotest ages where human remains or relics, or other more indirect evidence, justifies the opinion that man existed. Far back in these prehistoric periods, the problem of Quaternary man turns on the presence of his rude stone implements in the drift gravels and in caves, associated with the remains of what may be called for shortness the mammoth-fauna. Not to recapitulate details which have been set down in a hundred books, the point to be insisted on is how, in the experience of those who, like myself, have followed them since the time of Boucher de Perthes, the effect of a quarter of a century's research and criticism has been to give Quaternary man a more and more real position. The clumsy flint pick and its contemporary mammoth-tooth have become stock articles in museums, and every year adds new localities where palæolithic implements are found of the types catalogued years ago by Evans, and in beds agreeing with the sections drawn years ago by Prestwich. It is generally admitted that about the close of the Glacial period savage man killed the huge maned elephants, or fled from the great lions and tigers, on what was then forest-clad valley bottom, in ages before the later waterflow had cut out the present wide valleys 50 or 100 feet or more lower, leaving the remains of the ancient drift-beds exposed high on what are now the slopes. To fix our ideas on the picture of an actual locality, we may fancy ourselves standing with Mr. Spurrell on the old sandy beach of the Thames near Crayford, 35 feet above where the river now flows two miles away in the valley. Here we are on the very workshop-floor where palæolithic man sat chipping at the blocks of flint which had fallen out of the chalk cliff above his head. There lie the broken remains of his blocks, the flint chips he knocked off, and which can be fitted back into their places, the striking-stones with which the flaking was done; and with these the splintered bones of mammoth and tichorhine rhinoceros, possibly remains of meals. Moreover, as if to point the contrast between the rude palæolithic man who worked these coarse blocks, and apparently never troubled himself to seek for better material, the modern visitor sees within fifty yards of the spot the bottle-shaped pits dug out in later ages by neolithic man through the soil to a depth in the chalk where a layer of good workable flint supplied him with the material for his neat flakes and trimly-chipped arrow-heads. The evidence of caverns such as those of Devonshire and Perigord, with their revelations of early European life and art, has been supplemented by many new explorations, without shaking the conclusion arrived at as to the age known as the reindeer period of the northern half of Europe, when the mammoth and cave-bear and their contemporary mammals had not yet disappeared, but the close of the Glacial period was merging into the times when in England and France savages hunted the reindeer for food as the Arctic tribes of America do still. Human remains of these early periods are still scarce and unsatisfactory for determining race-types. Among the latest finds is part of a skull from the loess, at Podbaba, near Prague, with prominent brow-ridges, though less remarkable in this way than the celebrated Neanderthal skull. It remains the prevailing opinion of anatomists that these very ancient skulls are not apt to show extreme lowness of type, but to be higher in the scale than, for instance, the Tasmanian. The evidence increases as to the wide range of palæolithic man. He extended far into Asia, where his characteristic rude stone implements are plentifully found in the caves of Syria and the foot-hills of Madras. The question which this Section may have especial means of dealing with is whether man likewise inhabited America with the great extinct animals of the Quaternary period, if not even earlier.

Among the statements brought forward as to this subject, a few are mere fictions, while others, though entirely genuine, are surrounded with doubts, making it difficult to use them for anthropological purposes. We shall not discuss the sandalled human giants, whose footprints, 20 inches long, are declared to have been found with the footprints of mammoths, among whom they walked, at Carson, Nevada. There is something picturesque in the idea of a man in a past geological period finding on the Pampas the body of a glyptodon, scooping out its flesh, setting up its carapace on the ground like a monstrous dish-cover, and digging himself a burrow to live in underneath this animal roof; but geologists have not accepted the account. Even in the case of so well-known an explorer as the late Dr. Lund, opinions are still divided as to whether his human skulls from the caves of Brazil are really contemporary with the bones of megatherium and the fossil horse. One of the latest judgments has been favourable: Quatrefages not only looks upon the cave-skulls as of high antiquity, but regards their owners as representing the ancestors of the living Indians. The high and narrow dimensions of the ancient and modern skulls are given in the "Crania Ethnica," and whatever a similarity of proportions between them may prove, it certainly exists. Dr. Koch's celebrated flint arrow-head, recorded to have been found under the leg-bones of a mastodon in Missouri, is still to be seen, and has all the appearance of a modern Indian weapon, which raises doubt of its being really of the mastodon period. This antecedent improbability of remote geological age is felt still more strongly to attach to the stone pestles and mortars, &c., brought forward by Mr. J. D. Whitney, of the California Geological Survey, as found by miners in the gold-bearing gravels. On the one hand, these elaborate articles of stone-work are the very characteristic objects of the Indian graves of the district, and on the other the theory that the auriferous gravels capped by lava-flows are of Tertiary age is absolutely denied by geologists such as M. Jules Marcou in his article on "The Geology of California" (*Bull. Soc. Géol. de France*, 1883). It is to be hoped that the Section may have the opportunity of discussing Dr. C. C. Abbott's implements from Trenton, New Jersey. The turtle back celts, as they are called from their flat and convex sides, are rudely chipped from pebbles of the hard argillite out of the boulder-bed, but the question is as to the position of the sand and gravel in which they are found in the bluffs high above the present Delaware River. The first opinion come to, that the makers of the implements inhabited America not merely after but during the great Ice Age, has been modified by further examination, especially by the report of Mr. H. Carvill Lewis, who considers the implement-bearing bed not to have been deposited by a river which flowed over the top of the boulder-bed, but that, at a later period than this would involve, the Delaware had cut a channel through the boulder-bed, and that a subsequent glacier-flood threw down sand and gravel in this cutting at a considerable height above the existing river, burying therein the rude stone implements of an Esquimaux race then inhabiting the country. Belt, Wilson, and Putnam have written on this question, which I will not pursue further, except by pointing out that the evidence from the bluffs of the Delaware must not be taken by itself, but in connection with that from the terraces high above the James River, near Richmond, where Mr. C. M. Wallace has likewise reported the finding of rude stone instruments, to which must be added other finds from Guanajuato, Rio Juchipila, and other Mexican localities.

This leads at once into the interesting argument how far any existing people are the descendants and representatives of man of the Post-Glacial period. The problem whether the present Esquimaux are such a remnant of an early race is one which Prof. Boyd Dawkins has long worked at, and will, I trust, bring forward with full detail in this appropriate place. Since he stated this view in his work on "Cave-Hunting," it has continually been cited, whether by way of affirmation or denial, but always with that gain to the subject which arises from a theory based on distinct facts. May I take occasion here to mention

as preliminary the question, Were the natives met with by the Scandinavian seafarers of the eleventh century Esquimaux, and whereabouts on the coast were they actually found? It may be to Canadians a curious subject of contemplation how about that time of history Scandinavia stretched out its hands at once to their old and their new home. When the race of bold sea-rovers who ruled Normandy and invaded England turned their prows into the northern and western sea, they passed from Iceland to yet more inclement Greenland, and thence, according to Icelandic records, which are too consistent to be refused belief as to main facts, they sailed some way down the American coast. But where are we to look for the most southerly points which the Sagas mention as reached in Vineland? Where was Keelness, where Thorvald's ship ran aground, and Cross-ness, where he was buried, when he died by the *skräling's* arrow? Rafn, in the "Antiquitates Americanæ," confidently maps out these places about the promontory of Cape Cod, in Massachusetts, and this has been repeated since from book to book. I must plead guilty to having cited Rafn's map before now, but when with reference to the present meeting I consulted our learned editor of Scandinavian records at Oxford, Mr. Gudbrand Vigfusson, and afterwards went through the original passages in the Sagas with Mr. York Powell, I am bound to say that the voyages of the Northmen ought to be reduced to more moderate limits. It appears that they crossed from Greenland to Labrador (Helluland), and thence sailing more or less south and west, in two stretches of two days each they came to a place near where wild grapes grew, whence they called the country Vineland. This would, therefore, seem to have been somewhere about the Gulf of St. Lawrence, and it would be an interesting object for a yachting cruise to try down from the east coast of Labrador a fair four days' sail of a Viking ship, and identify, if possible, the sound between the island and the ness, the river running out of the lake into the sea, the long stretches of sand, and the other local features mentioned in the Sagas. While this is in the printers' hands, I hear that a paper somewhat to this same effect may come before the Geographical Section, but the matter concerns us here as bearing on the southern limit of the Esquimaux. The *skrälings* who came on the sea in skin canoes (*huthkeipr*), and hurled their spears with slings (*valslöngva*), seem by these very facts to have been probably Esquimaux, and the mention of their being swarthy, with great eyes and broad cheeks, agrees tolerably with this. The statement usually made that the word *skräling* meant "dwarf" would, if correct, have settled the question; but, unfortunately, there is no real warrant for this etymology. If we may take it that Esquimaux 800 years ago, before they had ever found their way to Greenland, were hunting seals on the coast of Newfoundland, and cariboo in the forest, their life need not have been very unlike what it is now in their Arctic home. Some day, perhaps, the St. Lawrence and Newfoundland shores will be searched for relics of Esquimaux life, as has been done with such success in the Aleutian Islands by Mr. W. H. Dall, though on this side of the continent we can hardly expect to find, as he does, traces of long residence, and rise from a still lower condition.

Surveying now the vast series of so-called native, or indigenous, tribes of North and South America, we may admit that the fundamental notion on which American anthropology has to be treated is its relation to Asiatic. This kind of research is, as we know, quite old, but the recent advances of zoology and geology have given it new breadth as well as facility. The theories which account for the wide-lying American tribes, disconnected by language as they are, as all descended from ancestors who came by sea in boats, or across Behring's Straits on the ice, may be felt somewhat to strain the probabilities of migration, and are likely to be remodelled under the information now supplied by geology as to the distribution of animals. It has become a familiar fact that the Equidæ, or horse-like animals, belong even more remarkably to the New than to the Old World. There was plainly land-connection between America and Asia for the horses whose remains are fossil in America to have been genetically connected with the horses re-introduced from Europe. The deer may have passed from the Old World into North America in the Pliocene period; and the opinion is strongly held that the camels came the other way, originating in America and spreading thence into Asia and Africa. The mammoth and the reindeer did not cross over a few thousand years ago by Behring's Straits, for they had been since Pleistocene times spread over the north of what was then one continent. To realise this ancient land-junction of Asia and America, this "Tertiary-bridge," to use Prof. Marsh's expression, it is instructive to look at Mr. Wallace's chart of the present soundings, observing that an elevation of under 200 feet would make Behring's Straits land, while moderately shallow sea extends southward to about the line of the Aleutian Islands, below which comes the plunge into the ocean depths. If, then, we are to consider America as having received its human population by ordinary migration of successive tribes along this highway, the importance is obvious of deciding how old man is in America, and how long the continent remained united with Asia, as well as how these two difficult questions are bound up together in their bearing on anthropology. Leaving them to be settled by more competent judges, I will only point out that the theory of northern migration on dry land is after all only a revival of an old opinion which came naturally to Acosta in the sixteenth century, because Behring's Straits were not yet known of, and was held by Buffon in the eighteenth, because the zoological conditions compelled him to suppose that Behring's Straits had not always been there. Such a theory, whatever the exact shape it may take, seems wanted for the explanation of that most obvious fact of anthropology, the analogy of the indigenes of America with Asiatics, and more especially with East and North Asiatics or Mongoloids. This broad race-generalisation has thrust itself on every observer, and each has an instance to mention. My own particular instance is derived from inspection of a party of Botocudo Indians lately exhibited in London, who in proper clothing could have passed without question as Thibetans or Siamese. Now when ethnologists like Dr. Pickering remark on the South Asiatic appearance of Californian tribes, it is open to them to argue that Japanese sailors of junks wrecked on the coast may have founded families there. But the Botocudos are far south and on the other side of the Andes, rude dwellers in the forests of Brazil, and yet they exhibit in an extreme form the Mongoloid character which makes America to the anthropologist part and parcel of Asia. Looked at in this light, there is something suggestive in our still giving to the natives of America the name of Indians; the idea of Columbus that the Caribs were Asiatics was not so absurd after all.

It is perhaps hardly needful now to protest against stretching the generalisation of American uniformity too far, and taking literally Humboldt's saying that he who has seen one American has seen all. The common character of American tribes, from Hudson's Bay to Tierra del Fuego, though more homogeneous than on any other tract of the world of similar extent, admits of wide subvariation. How to distinguish and measure this subvariation is a problem in which anthropology has only reached unsatisfactory results. The broad distinctions which are plainly seen are also those which are readily defined, such as the shape of the nose, curve of the lips, or the projection of the cheekbones. But all who have compared such American races as Aztecs and Ojibwas must be sensible of extreme difficulty in measuring the proportions of an average facial type. The attempt to give in a single pair of portraits a generalised national type has been tried—for instance, in the St. Petersburg set of models of races at the Exhibition of 1862. But done merely by eye, as they were, they were not so good as well-chosen individual portraits. It would be most desirable that Mr. Francis Galton's method of photographs superposed so as to combine a group of individuals into one generalised portrait, should have a thorough trial on groups of Iroquois, Aztecs, Caribs, and other tribes who are so far homogeneous in feature as to lend themselves to form an abstract portrait. A set of American races thus "Galtonised" (if I may coin the term) would very likely be so distinctive as to be accepted in anthropology. Craniological measurement has been largely applied in America, but unfortunately it was set wrong for years by the same misleading tendency to find a uniformity not really existent. Those who wish to judge Morton's dictum applied to the Scioto Mound skull, "the perfect type of Indian conformation, to which the skulls of all the tribes from Cape Horn to Canada more or less approximate," will find facts to the contrary set forth in Chap. XX. of Wilson's "Prehistoric Man," and in Quatrefages and Hamy, "Crania Ethnica." American crania really differ so much that the hypothesis of successive migrations has been brought in to account for the brachycephalic skulls of the mound-builders as compared with living Indians of the district. Among minor race-divisions, as one of the best established may be mentioned that which in this district brings the Algonquin and Iroquois together into the dolichocephalic division;

yet even here some divide the Algonquins into two groups by their varying breadth of skull. What may be the interpretation of the cranial evidence as bearing on the American problem it would be premature to say; at present all that can be done is to systematise facts. It is undisputed that the Esquimaux in their complexion, hair, and features approximate to the Mongoloid type of North Asia; but when it comes to cranial measurement the Esquimaux, with their narrower skulls, whose proportion of breadth to length is only 75 to 80, are far from conforming to the broad-skulled type of North Asiatic Mongoloids, whose average index is toward 85. Of this divergence I have no explanation to offer; it illustrates the difficulties which have to be met by a young and imperfect science.

To clear the obscurity of race-problems, as viewed from the anatomical standing point, we naturally seek the help of language. Of late years the anthropology of the Old World has had ever-increasing help from comparative philology. In such investigations, when the philologist seeks a connection between the languages of distant regions, he endeavours to establish both a common stock of words and a common grammatical structure. For instance, this most perfect proof of connection has been lately adduced by Mr. R. H. Codrington in support of the view that the Melanesians and Polynesians, much as they differ in skin and hair, speak languages which belong to a common stock. A more adventurous theory is that of Lenormant and Sayce, that the old Chaldean language is connected with the Tatar group; yet even here there is an *a priori* case based at once on analogies of dictionary and grammar. The comparative method becomes much weaker when few or no words can be claimed as similar, and the whole burden of proof has to be borne by similar modes of word-formation and syntax, as, for example, in the researches of Aymonier and Keane tending to trace the Malay group of languages into connection with the Khmer or Cambodian. Within America the philologist uses with success the strong method of combined dictionary and grammar in order to define his great language-groups, such as the Algonquin, extending from Hudson's Bay to Virginia, the Athabascan, from Hudson's Bay to New Mexico, both crossing Canada in their vast range. But attempts to trace analogies between lists of words in Asiatic and American languages, though they may have shown some similarities deserving further inquiry, have hardly proved an amount of correspondence beyond what chance coincidence would be capable of producing. Thus when it comes to judging of affinities between the great American language-families, or of any of them, with the Asiatic, there is only the weaker method of structure to fall back on. Here the Esquimaux analogy seems to be with North Asiatic languages. It would be defined as agglutinative-suffixing, or, to put the definition practically, an Esquimaux word of however portentous length, is treated by looking out in the dictionary the first syllable or two, which will be the root, the rest being a string of modifying suffixes. The Esquimaux thus presents in an exaggerated form the characteristic structure of the vast Ural-Altaic or Turanian group of Asiatic languages. In studying American languages as a whole, the first step is to discard the generalisation of Duponceau as to the American languages from Greenland to Cape Horn being united together, and distinguished from those of other parts of the world by a common character of polysynthetism, or combining whole sentences into words. The real divergences of structure in American language-families are brought clearly into view in the two dissertations of M. Lucien Adam, which are the most valuable papers of the Congrès International des Americanistes. Making special examination of sixteen languages of North and South America, Adam considers these to belong to a number of independent or irreducible families, as they would have been, he says, "had there been primitively several human couples." It may be worth suggesting, however, that the task of the philologer is to exhaust every possibility of discovering connections between languages before falling back on the extreme hypothesis of independent origins. These American language-families have grammatical tendencies in common, which suggest original relationship, and in some of these even correspond with languages of other regions in a way which may indicate connection rather than chance. For instance, the distinction of gender, not by sex as male and female, but by life as animate and inanimate, is familiar in the Algonquin group; in Cree *muskesin* = shoe (mocassin) makes its plural *muskesină*, while *eskwayŭ* = woman (squaw) makes its plural *eskwaywuk*. Now, this kind of gender is not peculiar to America, but appears in South-East Asia, as for instance in the Kol languages of Bengal. In that Asiatic district also appears the habit of infixing, that is, of modifying roots or words by the insertion of a letter or syllable, somewhat as the Dakota language inserts a pronoun within the verb-root itself, or as that remarkable language, the Chocta, alters its verbs by insertions of a still more violent character. Again, the distinction between the inclusive and exclusive pronoun *we*, according as it means "You and I" or "they and I," &c. (the want of which is perhaps a defect in English), is as familiar to the Maori as to the Ojibwa. Whether the languages of the American tribes be regarded as derived from Asia or as separate developments, their long existence on the American continent seems unquestionable. Had they been the tongues of tribes come within a short time by Behring's Straits, we should have expected them to show clear connection with the tongues of their kindred left behind in Asia, just as the Lapp in Europe, whose ancestors have been separated for thousands of years from the ancestors of the Ostyak or the Turk, still shows in his speech the traces of their remote kinship. The problem how tribes so similar in physical type and culture as the Algonquins, Iroquois, Sioux, and Athabascans, should adjoin one another, yet speaking languages so separate, is only soluble by influences which have had a long period of time to work in.

The comparison of peoples according to their social framework of family and tribe has been assuming more and more importance since it was brought forward by Bachofen, McLennan, and Morgan. One of its broadest distinctions comes into view within the Dominion of Canada. The Esquimaux are patriarchal, the father being head of the family, and descent and inheritance following the male line. But the Indian tribes further south are largely matriarchal, reckoning descent not on the father's but the mother's side. In fact, it was through becoming an adopted Iroquois that Morgan became aware of this system, so foreign to European ideas, and which he supposed at first to be an isolated peculiarity. No less a person than Herodotus had fallen into the same mistake over 2000 years ago, when he thought the Lykians, in taking their names from their mothers, were unlike all other men. It is now, however, an accepted matter of anthropology that in Herodotus's time nations of the civilised world had passed through this matriarchal stage, as appears from the survivals of it retained in the midst of their newer patriarchal institutions. For instance, among the Arabs to this day, strongly patriarchal as their society is in most respects, there survives that most matriarchal idea that one's nearest relative is not one's father but one's maternal uncle; he is bound to his sister's children by a "closer and holier tie" than paternity, as Tacitus says of the same conception among the ancient Germans. Obviously great interest attaches to any accounts of existing tribes which preserve for us the explanation of such social phenomena. Some of the most instructive of these are too new to have yet found their way into our treatises on early institutions; they are accounts lately published by Dutch officials among the non-Islamised clans of Sumatra and Java. G. A. Wilken, "Over de Verwantschap en het Huwelijks en Erfrecht bij de Volken van den Indischen Archipel," summarises the account put on record by Van Hasselt as to the life of the Malays of the Padang Highlands of Mid-Sumatra, who are known to represent an early Malay population. Among these people not only kinship but habitation follows absolutely the female line, so that the numerous dwellers in one great house are all connected by descent from one mother, one generation above another, children, then mothers and maternal uncles and aunts, then grandmothers and maternal great-uncles and great-aunts, &c. There are in each district several *suku* or mother-clans, between persons born in which marriage is forbidden. Here then appear the two well-known rules of female descent and exogamy, but now we come into view of the remarkable state of society that, though marriage exists, it does not form the household. The woman remains in the maternal house she was born in, and the man remains in his; his position is that of an authorised visitor; if he will, he may come over and help her in the rice-field, but he need not; over the children he has no control whatever, and were he to presume to order or chastise them, their natural guardian, the mother's brother (*mamak*), would resent it as an affront. The law of female descent and its connected rules have as yet been mostly studied among the native Americans and Australians, where they have evidently undergone much modification. Thus 150 years ago Father Lafitau mentions that the husband and wife, while in fact moving into one another's hut, or setting up a new one, still kept up the matriarchal idea by the fiction that neither he nor she quitted

their own maternal house. But in the Sumatra district just referred to, the matriarchal system may still be seen in actual existence, in a most extreme and probably early form. If, led by such new evidence, we look at the map of the world from this point of view, there discloses itself a remarkable fact of social geography. It is seen that matriarchal exogamous society, that is, society with female descent and prohibition of marriage within the clan, does not crop up here and there, as if it were an isolated invention, but characterises a whole vast region of the world. If the Malay district be taken as a centre, the system of intermarrying mother-clans may be followed westward into Asia, among the Garos and other hill-tribes of India. Eastward from the Indian Archipelago it pervades the Melanesian islands, with remains in Polynesia; it prevails widely in Australia, and stretches north and south in the Americas. This immense district represents an area of lower culture, where matriarchalism has only in places yielded to the patriarchal system, which develops with the idea of property, and which, in the other and more civilised half of the globe, has carried all before it, only showing in isolated spots and by relics of custom the former existence of matriarchal society. Such a geographical view of the matriarchal region makes intelligible facts which while not thus seen together were most puzzling. When years ago Sir George Grey studied the customs of the Australians, it seemed to him a singular coincidence that a man whose maternal family name was Kangaroo might not marry a woman of the same name, just as if he had been a Huron of the Bear or Turtle totem, prohibited accordingly from taking a wife of the same. But when we have the facts more completely before us, Australia and Canada are seen to be only the far ends of a world-district pervaded by these ideas, and the problem becomes such a one as naturalists are quite accustomed to. Though Montreal and Melbourne are far apart, it may be that in prehistoric times they were both connected with Asia by lines of social institution as real as those which modern times connect them through Europe. Though it is only of late that this problem of ancient society has received the attention it deserves, it is but fair to mention how long ago its scientific study began in the part of the world where we are assembled. Father Lafitau, whose "Mœurs des Sauvages Amériquains" was published in 1724, carefully describes among the Iroquois and Hurons the system of kinship to which Morgan has since given the name of "classificatory," where the mother's sisters are reckoned as mothers, and so on. It markable to find this acute Jesuit missionary already pointing out how the idea of the husband being an intruder in his wife's house bears on the pretence of surreptitiousness in marriage among the Spartans. He even rationally interprets in this way a custom which to us seems fantastic, but which is a most serious observance among rude tribes widely spread over the world. A usual form of this custom is that the husband and his parents-in-law, especially his mother-in-law, consider it shameful to speak to or look at one another, hiding themselves or getting out of the way, at least in pretence, if they meet. The comic absurdity of these scenes, such as Tanner describes among the Assiniboins, disappears if they are to be understood as a legal ceremony, implying that the husband has nothing to do with his wife's family. To this part of the world also belongs a word which has been more effective than any treatise in bringing the matriarchal system of society into notice. This is the term *totem*, introduced by Schoolcraft to describe the mother-clans of the Algonquins, named "Wolf," "Bear," &c. Unluckily the word is wrongly made. Prof. Max Muller has lately called attention to the remark of the Canadian philologist Father Cuoq (N. O. Ancien Missionnaire), that the word is properly *ote*, meaning "family mark," possessive *otem*, and with the personal pronoun *nind otem*, "my family mark," *kit otem*, "thy family mark." It may be seen in Schoolcraft's own sketch of Algonquin grammar how he erroneously made from these a word *totem*, and the question ought perhaps to be gone into in this Section, whether the term had best be kept up or amended, or a new term substituted. It is quite worth while to discuss the name, considering what an important question of anthropology is involved in the institution it expresses. In this region there were found Iroquois, Algonquins, Dakotas, separate in language, and yet whose social life was regulated by the matriarchal totem structure. May it not be inferred from such a state of things that social institutions form a deeper-lying element in man than language or even physical race-type? This is a problem which presents itself for serious discussion when the evidence can be brought more completely together.

It is obvious that in this speculation, as in other problems now presenting themselves in anthropology, the question of the antiquity of man lies at the basis. Of late no great progress has been made toward fixing a scale of calculation of the human period, but the arguments as to time required for alterations in valley-levels, changes of fauna, evolution of races, languages, and culture, seem to converge more conclusively than ever toward a human period short indeed as a fraction of geological time, but long as compared with historical or chronological time. While, however, it is felt that length of time need not debar the anthropologist from hypotheses of development and migration, there is more caution as to assumptions of millions of years where no arithmetical basis exists, and less tendency to treat everything prehistoric as necessarily of extreme antiquity, such as, for instance, the Swiss lake-dwellings and the Central American temples. There are certain problems of American anthropology which are not the less interesting for involving no considerations of high antiquity; indeed they have the advantage of being within the check of history, though not themselves belonging to it.

Humboldt's argument as to traces of Asiatic influence in Mexico is one of these. The four ages in the Aztec picture-writings, ending with catastrophes of the four elements, earth, fire, air, water, compared by him with the same scheme among the Banyans of Surat, is a strong piece of evidence which would become yet stronger if the Hindoo book could be found from which the account is declared to have been taken. Not less cogent is his comparison of the zodiacs or calendar-cycles of Mexico and Central America with those of Eastern Asia, such as that by which the Japanese reckon the Sixty-year cycle by combining the elements seriatim with the twelve animals, Mouse, Bull, Tiger, Hare, &c.; the present year is, I suppose, the second water-ape year, and the time of day is the goat-hour. Humboldt's case may be reinforced by the consideration of the magical employment of these zodiacs in the Old and New World. The description of a Mexican astrologer, sent for to make the arrangements for a marriage by comparing the zodiac animals of the birthdays of bride and bridegroom, might have been written almost exactly of the modern Kalmuks; and in fact it seems connected in origin with similar rules in our own books of astrology. Magic is of great value in thus tracing communication, direct or indirect, between distant nations. The power of lasting and travelling which it possesses may be instanced by the rock-pictures from the sacred Roches Percées of Manitoba, sketched by Dr. Dawson, and published in his father's volume on "Fossil Man," with the proper caution that the pictures, or some of them, may be modern. Besides the rude pictures of deer and Indians and their huts, one sees with surprise a pentagram more neatly drawn than that defective one which let Mephistopheles pass Faust's threshold, though it kept the demon in when he had got there. Whether the Indians of Manitoba learnt the magic figure from the white man, or whether the white man did it himself in jest, it proves a line of intercourse stretching back 2500 years to the time when it was first drawn as a geometrical diagram of the school of Pythagoras. To return to Humboldt's argument, if there was communication from Asia to Mexico before the Spanish Conquest, it ought to have brought other things, and no things travel more easily than games. I noticed some years ago that the Aztecs are described by the old Spanish writers as playing a game called *patolli*, where they moved stones on the squares of a cross-shaped mat, according to the throws of beans marked on one side. The description minutely corresponds with the Hindoo game of *pachisi*, played in like manner with cowries instead of beans; this game, which is an early variety of backgammon, is well known in Asia, whence it seems to have found its way into America. From Mexico it passed into Sonora and Zacatecas, much broken down, but retaining its name, and it may be traced still further into the game of plum-stones among the Iroquois and other tribes. Now, if the probability be granted that these various American notions came from Asia, their importation would not have to do with any remotely ancient connection between the two continents. The Hindoo element-catastrophes, the East Asiatic zodiac-calendars, the game of backgammon, seem none of them extremely old, and it may not be a thousand years since they reached America. These are cases in which we may reasonably suppose communication by seafarers, perhaps even in some of those junks which are brought across so often by the ocean-current and wrecked on the Californian coast. In connection with ideas borrowed from Asia here arises the question, How did the Mexicans and

Peruvians become possessed of bronze? Seeing how imperfectly it had established itself, not even dispossessing the stone implements, I have long believed it to be an Asiatic importation of no great antiquity, and it is with great satisfaction that I find such an authority on prehistoric archæology as Prof. Worsaae comparing the bronze implements in China and Japan with those of Mexico and Peru, and declaring emphatically his opinion that bronze was a modern novelty introduced into America. While these items of Asiatic culture in America are so localised as to agree best with the hypothesis of communication far south across the Pacific, there are others which agree best with the routes far north. A remarkable piece of evidence pointed out by General Pitt-Rivers is the geographical distribution of the Tatar or composite bow, which in construction is unlike the long-bow, being made of several pieces spliced together, and which is bent backwards to string it. This distinctly Asiatic form may be followed across the region of Behring's Straits into America among the Esquimaux and northern Indians, so that it can hardly be doubted that its coming into America was by a northern line of migration. This important movement in culture may have taken place in remotely ancient times.

A brief account may now be given of the present state of information as to movements of civilisation within the doubl continent of America. Conspicuous among these is what may be called the northward drift of civilisation which comes well into view in the evidence of botanists as to cultivated plants. Maize, though allied to, and probably genetically connected with, an Old World graminaceous family, is distinctly American, and is believed by De Candolle to have been brought into cultivation in Peru, whence it was carried from tribe to tribe up into the north. To see how closely the two continents are connected in civilisation, one need only look at the distribution on both of maize, tobacco, and cacao. It is admitted as probable that from the Mexican and Central American region agriculture travelled northward, and became established among the native tribes. This direction may be clearly traced in a sketch of their agriculture, such as is given in Mr. Lucien Carr's paper on the "Mounds of the Mississippi Valley." The same staple cultivation passed on from place to place, maize, haricots, pumpkins, for food, and tobacco for luxury. Agriculture among the Indians of the great lakes is plainly seen to have been an imported craft by the way in which it had spread to some tribes but not to others. The distribution of the potter's art is similarly partial, some tribes making good earthen vessels, while others still boiled meat in its own skin with hot stones, so that it may well be supposed that the arts of growing corn and making the earthen pot to boil the hominy came together from the more civilised nations of the south. With this northward drift of civilisation other facts harmonise. The researches of Buschmann, published by the Berlin Academy, show how Aztec words have become embedded in the languages of Sonora, New Mexico, and up the western side of the continent, which could not have spread there without Mexican intercourse extending far north-west. This indeed has left many traces still discernible in the industrial and decorative arts of the Pueblo Indians. Along the courses of this northward drift of culture remain two remarkable series of structures probably connected with it. The Casas Grandes, the fortified communal barracks (if I may so call them) which provided house-room for hundreds of families, excited the astonishment of the early Spanish explorers, but are only beginning to be thoroughly described now that such districts as the Taos Valley have come within reach by the railroads across to the Pacific. The accounts of these village-forts and their inhabitants, drawn up by Major J. W. Powell, of the Bureau of Ethnology, and Mr. Putnam of the Peabody Museum, disclose the old communistic society surviving in modern times, in instructive comment on the philosophers who are seeking to return to it. It would be premature in the present state of information to decide whether Mr. J. L. Morgan, in his work on the "Houses and House-life of the American Aborigines," has realised the conditions of the problem. It is plausible to suppose with him a connection between the communal dwellings of the American Indians, such as the Iroquois long-house with its many family hearths, with the more solid buildings inhabited on a similar social principle by tribes such as the Zuñis of New Mexico. Morgan was so much a man of genius, that his speculations, even when at variance with the general view of the facts, are always suggestive. This is the case with his attempt to account for the organisation of the Aztec State as a highly-developed Indian tribal community, and even to explain the many-roomed stone palaces, as they are called, of Central America, as being huge communal dwellings like those of the Pueblo Indians. I will not go further into the subject here, hoping that it may be debated in the Section by those far better acquainted with the evidence. I need not, for the same reason, do much more than mention the mound-builders, nor enter largely on the literature which has grown up about them since the publication of the works of Squier and Davis. Now that the idea of their being a separate race of high antiquity has died out, and their earthworks with the implements and ornaments found among them are brought into comparison with those of other tribes of the country, they have settled into representatives of one of the most notable stages of the northward drift of culture among the indigenes of America.

Concluding this long survey, we come to the practical question how the stimulus of the present meeting may be used to promote anthropology in Canada. It is not as if the work were new here; indeed some of its best evidence has been gathered on this ground from the days of the French missionaries of the seventeenth century. Naturally, in this part of the country, the rudimentary stages of thought then to be found among th Indians have mostly disappeared. For instance, in the native conceptions of souls and spirits the crudest animistic ideas were in full force. Dreams were looked on as real events, and the phantom of a living or a dead man seen in a dream was considered to be that man's personality and life, that is, his soul. Beyond this, by logical extension of the same train of thought, every animal or plant or object, inasmuch as its phantom could be seen away from its material body in dreams or visions, was held to have a soul. No one ever found this primitive conception in more perfect form than Father Lallemant, who describes, in the "Rélations des Jesuites" (1626), how, when the Indians burried kettles and furs with the dead, the bodies of these things remained, but the souls of them went to the dead men who used them. So Father Le Jeune describes the souls, not only of men and animals, but of hatchets and kettles, crossing the water to the Great Village out in the sunset. The genuineness of this idea of object-souls is proved by other independent explorers finding them elsewhere in the world. Two of the accounts most closely tallying with the American come from the Rev. Dr. Mason, in Burmah, and the Rev. J. Williams, in Fiji. That is to say, the most characteristic development of early animism belongs to the same region as the most characteristic development of matriarchal society, extending from South-East Asia into Melanesia and Polynesia, and North and South America. Every one who studies the history of human thought must see the value of such facts as these, and the importance of gathering them up among the rude tribes who preserve them, before they pass into a new stage of culture. All who have read Mr. Hale's studies on the Hiawatha legend and other Indian folk-lore, must admit that the native traditions, with their fragments of real history, and their incidental touches of native religion, ought never to be left to die out unrecorded. In the Dominion, especially in its outlying districts toward the Arctic region and over the Rocky Mountains, there is an enormous mass of anthropc logical material of high value to be collected, but this collection must be done within the next generation, or there will be littl left to collect. The small group of Canadian anthropologists, able and energetic as they are, can manage and control this work, but cannot do it all themselves. What is wanted is a Canadian Anthropological Society with a stronger organisation than yet exists, able to arrange explorations in promising districts, to circulate questions and requirements among the proper people in the proper places, and to lay a new burden on the shoulders of the already hard-worked professional men and other educated settlers through the newly-opened country, by making them investigators of local anthropology. The Canadian Government, which has well deserved the high reputation it holds throughout the world for wisdom and liberality in dealing with the native tribes, may reasonably be asked to support more thorough exploration, and collection and publication of the results, in friendly rivalry with the United States Government, which has in this way fully acknowledged the obligation of making the colonisation of new lands not only promotive of national wealth but serviceable to science. It is not for me to do more here, and now, than to suggest practical steps towards this end. My laying before the Section so diffusive a sketch of the problems of anthropology as they present themselves in the Dominion has been with the underlying intention of calling public notice to the important scientific work now standing ready to Canadian hands; the undertaking of which it is to be hoped will be one outcome of this visit of the British Association to Montreal.

COMETS[1]

FOR several months past I have anxiously considered how I could best discharge the honourable duty which has been intrusted to me this evening. I have to deliver an astronomical discourse, and to do my very utmost to make that discourse adequate to the subject, adequate to this large and cultivated audience, and adequate to the memorable occasion on which the British Association has first crossed the Atlantic Ocean.

I propose to address you this evening on the subject of comets, but it will be readily understood that, of a subject so vast and so elaborate, only a slender proportion can be comprised within a single lecture. The first question to be decided was how to select from the vast mass of materials those which would be most suitable for our discussion this evening. To describe the natural history of comets with any approach to completeness would be a very tedious, indeed almost an endless, task. We must rather select those episodes in the history which have especially added to our knowledge, and enabled us to obtain a rational view of the whole subject. Does not Longfellow tell us how impossible it would have been for him to portray the fortunes of Evangeline throughout every detail? He has only disclosed to us the picturesque and eventful phases of that history. May I be permitted to say that I desire to treat my subject in a similar manner, and while concentrating my attention on the really important matters I shall yet follow the wanderers' footsteps, "not through each devious path, each changeful year of existence."

In pursuance of this scheme I shall at a single blow lop off all the earlier parts of the history. The great primitive discoveries of the character of comets and of their movements must be entirely omitted. The splendid researches of Sir Isaac Newton, and the classical achievement of Halley, are among this class. They are no doubt familiar to every cultivated mind, for they belong to that wondrous alliance between mathematics and astronomy which imparts a thrill of pleasure to the generous intellect. They are not for our discussion to-night.

I shall only address you upon the more recent acquisitions to our knowledge of comets, and in order to give definiteness to our programme, I shall select a certain epoch not yet twenty years old, which is to bound our retrospect into time past. There is a special appropriateness in the choice of the year 1866 as a starting point for the modern history of comets. A very memorable occurrence in that year attracted universal attention, and threw much and quite unexpected light on the nature of comets. The review of the subject given in this lecture will extend from the year 1866 to the present time. But even in this restricted interval it will not be practicable for me to give anything like an exhaustive account of the different researches that have been made. Every astronomical journal teems with observations of comets. Every year brings us one, or two, or three, or more comets; organised efforts are made to observe these comets to the utmost, and each season has its own harvest of discoveries. Amid this host of claimants for our attention we must wend our way this evening, glancing at some discoveries, according to others such notice as their importance may merit, but reserving special attention for the three monumental achievements in the modern history of comets. These are, firstly, the determination of the connection between comets and shooting stars; secondly, the spectroscopic researches on comets; and thirdly, the investigations of the tails of comets. The first of these subjects must be for ever associated with the name of Professor Schiaparelli, the second with the name of Dr. Huggins, the third with the name of Professor Bredichin.

It was long ago remarked by Kepler, in language of splendid exaggeration, that there were as many comets in the heavens as there were fishes in the ocean. There are comets large and comets small, comets with one tail, comets with two tails, and comets without any tail at all. Comets appear at uncertain and irregular intervals, they are not confined to any special part of the heavens. A comet may be first discovered in one constellation, and after a journey across the heavens it may sink to invisibility in any other constellation. A comet is sometimes only seen for days or for weeks, but sometimes it remains visible for months or even for years. The features of the comet itself are also in a course of incessant transformation during its visit. Its size and its shape are not constant. The interval of a few days, or sometimes of even a few hours, suffices to work wondrous changes in a body almost spiritual in its texture.

Amid all these elements of confusion where are we to seek for the law and the order which really underlie the phenomena? There is law and there is order. Each one of the myriad comets pursues a definite high-road through space. It is in the province of the mathematician and the astronomer to ascertain by their joint labours what the path is for each comet. The astronomer directs his telescope to the comet, and he reads from the graduated circles attached to his telescope the precise point in the heavens where the comet is located. He repeats this observation a few nights later, he does it a third time, and his work is done. All the mathematician absolutely requires is to know the place of the comet accurately on three nights. He will no doubt be glad to accept further observations; they will help to eliminate the errors inseparable from such labours; they will enable him to obtain three places of the comet purged from all sources of uncertainty. The comet is then within his toils. He can determine the route which the comet is pursuing. He can by his calculations follow the comet in its movements through the profundity of space far beyond the penetration of the telescope. The telescope only watches the comet during a brief portion of its career, but the subtle eye of the mathematician seldom loses sight of a comet once detected. He watches it recede to its greatest distance; he knows when the comet begins to return; he sees how it gradually approaches the sun. He assigns the spot on the heavens where the comet is first to appear, and he tells the day and sometimes even the hour when the telescope will welcome the wanderer's return.

It has long been known that the highway of each comet is one of those graceful curves known to geometers as conic sections. The comets which appear only once sweep through our system in a curve which cannot be distinguished from a perfect parabola. The small but exceedingly interesting class of comets which return periodically revolve in the most beautiful of all curves—the ellipse. The supreme law of gravitation has ordained that the comets must follow a conic section whereof the sun lies at one of the foci. But subject to this imperative restriction the orbit of a comet may have every degree of variety. A comet may revolve in a path so small that it only requires three years to complete a revolution. Another comet moving in a much longer ellipse will require seventy-five years. There may be every intermediate gradation, and there are some cometary orbits so vast that the mighty journey cannot be accomplished in less than thousands of years, while there are others whose orbits stretch out to a distance so stupendous that we fail to follow them in their wanderings. The ellipses seem to be utterly interminable, and in the language of mathematics we say that the orbit is parabolic.

In order to enunciate the first of the great modern discoveries which we are to consider to-night, it is necessary to associate with each comet a certain particular elliptic path lying in a particular plane with a particular position in that plane, and with a particular magnitude. The comet is, in fact, to be identified by its path as its only permanent characteristic, for, though the comets may exist in myriads, yet no two comets follow the same course through space: such a contingency is too remote to be worthy of serious contemplation; it is, in fact, infinitely improbable.

There is not, I believe, a greater surprise in the whole of modern astronomy than the discovery of a myriad of small bodies stealthily accompanying a comet in its mighty journey, and the surprise is all the greater when we consider that in another aspect we have been long familiar with these small bodies, and we have called them shooting stars or luminous meteors. It was Schiaparelli who first demonstrated, in 1866, the wholly unlooked-for connection between the showers of shooting stars and the movements of comets.

Every one is familiar with the very beautiful spectacle of a shooting star, which is seen to flash into the air and vanish in a streak of splendour. These little bodies were long an enigma in astronomy, but they have gradually been subordinated to law and order. It has been found that the sun which controls the mighty Jupiter does not disdain to guide with equal care the tiny shooting stars, and their movements are now tolerably well known. The received doctrine about the shooting stars has stood the severest test known to science—that is, the test of fulfilled prediction. The first great prediction in this refined branch of astronomy was made about twenty years ago. It was foretold that a splendid shower of shooting stars would occur on the night of November 12th, 1866. All the world knows how triumphantly this prediction was fulfilled.

If I may be permitted, I would wish to narrate in a few words my own experience of that ever-memorable night. The details of that majestic spectacle have been engraved on my memory.

[1] Lecture by Prof. R. S. Ball, Astronomer-Royal for Ireland, at the Montreal meeting of the British Association.

I have had the good fortune to see other striking astronomical phenomena. The first was the glorious comet of 1858, the last was the transit of Venus in 1882; but I have no hesitation in saying that no phenomenon I have ever seen in the heavens, and no spectacle that I have ever witnessed on the earth, has impressed me so deeply and so profoundly as the great shower of shooting stars in 1866.

I was at that time astronomer to the late Earl of Rosse, at Parsonstown, and in the autumn of the year I attended my first meeting of the British Association at Nottingham. From the lips of my esteemed friend, Mr. James Glaisher, I learned that a great shooting star shower was to be anticipated on the 12th of November. The prediction could not be put forward with all the confidence that we have when the almanac foretells an eclipse. It was rather a venture, by which an important theory was to be put to a severe test.

On the ever-memorable night I was occupied as usual in observing nebulæ with the present Earl of Rosse at the great reflecting telescope. In the early part of the evening the sky was clear, and the night was dark; but no unusual phenomenon occurred until about ten o'clock. I was at that moment watching a nebula at the eye-piece, when I was startled by an exclamation from the assistant by my side. I looked up just in time to see a superb shooting star stream across the heavens. Soon came another star, and then another, and then in twos and in threes. We saw at once that the prediction was about to be verified. We ceased the observations with the telescope and ascended to the top of the wall, which forms one of the supports of the great telescope. This position commanded an extensive view of the heavens, and from it Lord Rosse and myself, on a beautiful starlight night, witnessed that gorgeous display of celestial fireworks which has given fresh impetus to astronomy.

It was not merely the incredible number of the shooting stars that was remarkable. They came no doubt in thousands which no man could number, but what was especially to be noticed was the intrinsic brilliancy of each individual star. There were innumerable meteors that night any one of which would ha elicited a note of admiration on any ordinary occasion. As the night wore on and the constellation of Leo climbed up from the east, then the display exhibited a very interesting and characteristic feature, for, as each shooting star was projected across the sky, the track which it followed was invariably directed from the constellation of Leo, nay, even from a particular point in that constellation. So marked a property of the shower suggests an appropriate name, and accordingly this particular group of shooting stars bears the not unpleasing name of the "Leonids."

It is easy to demonstrate that the apparent radiation of the meteors from a point is only the effect of perspective. They are really moving in parallel lines. Those parallel lines have a vanishing point, and that point is the radiant in the constellation of Leo. As we stood on the walls of the great telescope we saw the true character of the radiant most beautifully demonstrated. Those meteors which appeared close to the radiant pursued a track which was greatly foreshortened. A few that were actually at the radiant, or very close to it, had no visible track at all, they merely shone like a very rapidly variable star, which rose from invisibility to brilliancy, and then again declined to evanescence, all within the space of a very few seconds. In these exceptional cases we viewed the track of the stars "end on." They were, in fact, coming straight at us, but fortunately there was a kindly screen which shielded the earth that night from the awful meteoric tempest. Each one of those meteors hurries along with a velocity truly appalling; it is more than a hundred times swifter than the swiftest bullet that was ever fired from a rifle. It is really the demoniacal impetuosity of this velocity which is the source of the earth's safety. The meteor moving freely through space suddenly plunges into our atmosphere. Instantly a gigantic resisting force is aroused. The velocity of the meteor is checked, and the energy stored in that velocity is transformed into heat. That heat is enough to raise the body red hot, to raise it white hot, nay, even to drive the solid mass into a streak of harmless vapour. Of all the countless myriads of shooting stars which went to their destruction on that night, not one single particle has ever been recovered. These facts, when placed in the crucible of the mathematician, conduct him to a solution of the problem as to the nature of the great shooting star shower. It is to be remembered that the law of gravitation determines the movements of these bodies. The meteor, ere its disastrous collision with our atmosphere, must have been traversing the solitudes of space in an elliptic path with the sun in one of the foci. This is as true of a meteor the size of a grain of sand as it is of the earth or the planet Jupiter. The astronomer then approaches the question with the knowledge that the orbit of the meteors is an ellipse (or at all events one of the conic sections), but what the particular ellipse is must be decided by an appeal to the actual observations. The facts are simple enough: we note in the first place that the shower took place on the 12th of November, but on the 12th of November in each year, or on any other fixed date, the earth is always at a particular point of its annual journey round the sun. The stream of meteors must therefore pass through that particular point of space, and hence the search for the orbit is narrowed, for only ellipses which pass through this particular point can fulfil the conditions of the question. Another clue is afforded by the position of that point in Leo from which all the meteors seemed to radiate. The mathematician sees how to fit the ellipse so that it shall give the proper radiant. And now the question has been narrowed almost to the last point. One more appeal to observation and the ellipse will be absolutely known. All we must now learn is how long the swarm of meteors takes to complete the circuit of its mighty path. To answer this question profound historical research has been made by Prof. Newton, and a mathematical research has been made which has given additional lustre even to the name of Adams. The great showers of meteors have been shown to have occurred at intervals for the last 1,000 years. The earliest record was in the year 902, on the occasion of the death of the Moorish king Ibrahim bin-Ahmad. An old chronicle describes how the event was solemnised in the heavens no less than on the earth; he tells us how "that night there were seen as it were lances, an infinite number of stars which scattered themselves like rain to right and left, and that year was called the year of the stars." We now know that this exhibition was not, as the old chronicler thought, a miraculous compliment to the memory of the deceased prince, it was really only a shower of the Leonids, such a shower as appears every thirty-three years, such a shower as appeared in 1866, such a shower as may be anticipated in the year 1899.

By these researches the path followed by the Leonids has been completely determined. The plane of the ellipse, and every circumstance of its position, and its proportions have been reduced to numerical accuracy. The shoal of meteors pursue their path unseen by any astronomer, but the mathematician knows precisely where they are at this moment, and at every moment.

This point being gained a great discovery was made by Schiaparelli in 1866. About that time a comet was seen, this comet was duly observed, and the path which it followed was computed. There was nothing very remarkable about the comet, and it would not now be much remembered save for one most extraordinary circumstance which Schiaparelli was the first to proclaim. Like the shoal of meteors this comet also revolves in an elliptic path around the sun. This is a mere consequence of the law of gravitation and calls for no remark, but the fact that the two ellipses lie in the same plane is a very remarkable coincidence which could not be overlooked. When we further come to see that the two ellipses are of the same size and shape, when we see that they are placed in the same position, when we see, in fact, that the ellipse which is the orbit of the shooting stars is identical with the orbit of the comet, then we have obtained a result which ranks as one of the most striking astronomical discoveries that this century has witnessed.

The Leonids therefore travel through space precisely in the track of the comet of 1866. The question at once arises of the relation of the shoal of meteors to the comet. Is the shoal of meteors one thing and the comet another thing, and do both these things happen to be travelling in the same orbit without any necessary connection, or are we to suppose that the two objects, if not actually identical, are at all events very intimately connected? These are problems which, in the present state of our knowledge, it seems difficult to solve. I shall only lay down one or two principles which may help us to form a conclusion.

Whatever be the nature of comets, or the materials of which they are composed; whether they be faint or bright, large or small, periodic or parabolic; one fact is certain, their masses are all extremely small in comparison with their great dimensions. I shall indeed, at a later part of this lecture, show that comets seem to be almost imponderable when compared with the great masses of the sun and of the planets. The great bulk of a comet necessarily implies that many parts of it are at a considerable distance from its centre of mass. Hence for a double reason the

coherence of the parts of a comet arising from their mutual gravitation is an extremely feeble force. Each particle of the comet is directly solicited by the sun to pursue a path of its own, and if the forces of coherence be not adequate to overcome this tendency the comet must undergo a gradual degradation into separate parts. As the periodic time of the orbit of each part will vary, it will follow that the comet will be spread out in fragments along its path. It would seem that these small fragments constitute the meteors.

It is often supposed that meteorites, or solid bodies which actually tumble down on the earth, are connected with shooting stars, and hence it has been asserted, and even by very good authority, that meteorites are connected with comets, if not actually parts of comets. I merely mention this view for the purpose of saying that to me it seems quite unsupported by the facts. There is no reliable evidence, or indeed no evidence at all, that meteorites are connected with the periodic showers of shooting stars which alone are connected with the comets. This would not be the occasion to discuss the interesting question as to the origin of meteorites, but all the available facts seem to me to point to an origin on some body far more closely resembling a planet than a comet.

It is now about sixteen years since Dr. Huggins first turned his spectroscope upon these bodies, and showed that certain lines in the spectra of the comet of 1868 were identical with certain of the lines of carbon. Since then many comets have been observed and much valuable spectroscopic work has been done. This has been so often and so fully discussed that I do not now propose to dwell on the subject at length. It is, however, quite impossible to avoid a brief reference to one of the latest efforts of Dr. Huggins' marvellous skill. He has succeeded in inducing a comet to depict with absolute fidelity its spectrum on the photographic plate. That photograph has not only shown the lines which could be *seen* with the spectroscope, but it has also exhibited many other lines in the invisible part of the spectrum. The discussion of this photograph and of the bright lines and the dark lines it contains is full of interest, though here I shall only remark that it contains convincing evidence of the presence of carbon in this comet.

That a comet's tail should be directed away from the sun is a very remarkable and characteristic feature of this group of bodies. At the first glance it seems at variance with every received doctrine of astronomy. The great law of Nature which regulates the movements of the heavenly bodies is the law of attraction. The very movement of a comet in an elliptic path around the sun is in itself a demonstration that the comet is attracted by the sun.

While the comet as a whole is amenable to the law of gravitation, it is obvious that the materials, whatever they may be, which constitute the tail of the comet must be repelled by some force of an exceptional character. This force must sometimes be of very great intensity. Cases are not wanting where a comet, after darting in close to the sun, has actually whirled round the sun with the stupendous velocity of 300 miles a second, and in a few hours has commenced its outward journey. During this appalling swoop what has been the conduct of the tail of the comet? It seems necessary to believe that at the commencement the tail was streaming away for millions of miles on one side of the sun, while in a few hours the tail has gone completely round, so as to be extending for millions of miles in the opposite direction. No known laws of mechanics allow us to believe that the *same* tail is seen under circumstances so diverse. We are compelled to believe that the tail is constantly dissipated and constantly renewed. It would, in fact, seem that the tail of a comet was in some respects like the column of smoke ascending from a chimney—the column remains, but the particles of which that column consists are in perpetual transition.

In the study of this subject we have to make use of the interesting labours of Prof. Bredichin of Moscow. This accomplished astronomer has devoted himself for many years to the collection and to the discussion of all the known phenomena of comets' tails, and he has succeeded, I believe, in taking a considerable step in the solution of the problems involved. In the first place he has shown that there are different types of comets, and he has proceeded to classify them. There are, first of all, the comets with very long and very straight tails, such, for instance, as the comet of 1874, and many others. The next class included the tails of a scimitar shape. These are often of very great splendour, though not so long or so straight as those of the first type. The great comet of 1858 may be cited as an illustration of this class. The third and last class of comets' tails are very short and curved. It is to be observed that these tails sometimes exist in combination, so that a comet is often decorated with two tails of different types.

Once the form of the tail has been laid down, and the perihelion distance of the comet given, then the investigation of the forces adequate to the production of that tail is a problem admitting of numerical solution. It can be demonstrated that the straightest tail that ever streamed from a comet could be produced by a repulsive force not more than twelve times as great as the intensity of gravitation at the same distance. This number twelve will be the characteristic of tails of the first type. The tails of the second type vary within certain limits, but speaking generally, the repulsive force adequate to their production need not be more than about equal to the force of gravitation itself. The tails of the third type would be explained if the repulsive force were only the fifth part of gravity.

The next question that arises is as to the physical explanation of the repulsive force which produces these tails. We have to find this force of three different intensities, one about twelve times as great as gravity, one about equal to gravity, and one about a fifth of gravity. Before we postulate the existence of a new force of some unknown character, it is surely our duty to inquire whether there may not be some force already known which is competent to produce the phenomena. The best known repulsive force is of course that with which every one is familiar in connection with electricity. Electricity attracts electricity of an opposite type, while it repels that of the same type. We are also aware that in some mysterious manner the sun is connected with electricity. We know that the phenomena of terrestrial magnetism are connected with solar phenomena, and hence we are tempted to inquire whether the electricity of the sun may not offer an adequate explanation of the phenomenon of the comet's tail.

Let us suppose that the sun is attracting a distant body by virtue of gravitation, and at the same time repelling that body in virtue of the fact that the sun and the body are both charged with electricity of the same name. When the attracted body is one of large dimensions, the attraction will vastly exceed the repulsion, and indeed the latter may be entirely neglected in most cases. There is, however, a radical difference between the nature of the electrical forces and the nature of the gravitational forces. The latter are proportional to the masses of the attracting bodies, while the electrical forces are proportional to their surfaces. The mass varies as the cube of the linear measurements, while the surface only varies as the square. The relative efficiency of the electric repulsion in comparison with the gravitational attraction increases as the radius of the particle decreases. It must thus necessarily follow that no matter how great may be the preponderance of the power of gravitation on masses of finite dimensions, yet it must always be possible, other things being equal, to have a particle so small that the electrical repulsion shall exceed in any required ratio the intensity of the attraction of gravitation.

As the comet draws near the sun, the heat it experiences increases, so that the materials of the comet begin to dilate, and to be driven off into a vaporous condition. The matter is thus resolved into a state of extreme subdivision. These separate particles are charged with an electricity similar to that of the sun, and in virtue of their minuteness the intensity of that repulsion has become sufficient to sweep off the particles in a stream, and thus generate the tail.

Such is the modern view of the formation of comets' tails. Professor Bredichin has given good reasons for thinking that we can even discover the special ingredients which enter into the formation of each of the three types of tail. It seems, from the molecular nature of hydrogen, that this element is especially suitable for the tails of the first type. The tails of the second type seem to arise from some substances possessing the properties of hydrocarbons, while the tails of the third type contain some elements which seem to have a high atomic weight. The theory of Professor Bredichin is well illustrated by the comet of 1858. This comet, besides the majestic curved tail, the object of so much admiration, had a pair of long, faint, slender tails, streaming straight from the head. These two objects were doubtless the edges of a conical tail of the first type, too faint to be visible throughout its entire extent. The great tail was one of the second type.

We have many reasons for believing that the masses of comets are very much less than the masses of the planets. We

might indeed almost conclude that the masses of the comets are inappreciable. Let us briefly indicate the grounds for this important conclusion.

The sun and the planets form a system characterised by perfect order and symmetry. We have the sun in the centre. We have all the great planets moving round the sun in the same direction. They all move nearly in circles, and all these circles lie nearly in the same plane. This organisation is a necessary *modus vivendi* among the bodies of our system. Each planet acts and reacts upon all the other planets, but, owing to the circumstances of their movements, their irregularities are but small, and the permanence of the system is insured. Alter that system to any extent, merely reverse for example the direction in which one of the planets is moving, and the whole compromise is destroyed. The actions and reactions, instead of being quickly balanced, will go on accumulating, and the seeds of confusion and ultimate dissolution have been sown. But we have in our system thousands of comets which repudiate all the regulations by which the planetary convention is restrained. Comets come in what direction they please, they move in every plane but the right one, and their orbits are not in the least like circles. The very fact that our earth continues to revolve around the sun so as to be a fit abode for life, is a proof that comets cannot have any considerable mass. If comets had mass then organic disease would be introduced into the solar system which must ultimately prove fatal.

Science has gradually dissipated the fears which once invested comets: they are interesting and beautiful visitors which come to please and to instruct, never to threaten or to destroy.

NOTES

THE autumn Congress of the Sanitary Institute of Great Britain will be held this year at Dublin, and the programme of the proceedings has been issued. The President of the Congress is Sir Robert Rawlinson, C.B., who will open the Congress with an inaugural address on Tuesday the 30th inst., and the proceedings will last until October 4. The Congress is divided into three sections—the first, "Sanitary Science and Preventive Medicine"; the second, "Engineering and Architecture"; and the third, "Chemistry, Meteorology, and Geology." Of the first section, the president is the Registrar-General for Ireland, Mr. Thomas W. Grimshaw, M.A., M.D. In the section of "Engineering and Architecture," the president is the Engineering Inspector of the Local Government Board for Ireland, Mr. C. D. Cotton, C.E.; and the president of the section of "Chemistry, Meteorology, and Geology" is Mr. C. A. Cameron, M.D., the City Analyst and Superintendent Medical Officer of Health for Dublin. The sectional meetings and the general meetings will be held at Trinity College, where the opening address will be delivered on Tuesday evening by Sir Robert Rawlinson. On Wednesday morning the actual work of the Congress will commence with the address of the president of the first section, and the remainder of the day will be taken up with the reading of papers and their discussion, while a *conversazione* will be held in the evening. The business of the second section will be taken on Thursday, October 2, and in the evening a lecture will be delivered to the Congress by Dr. Alfred Carpenter on "Education by Proverb in Sanitary Work." On Friday, after the third section, the closing general meeting of the Congress will be held. Arrangements for excursions will be made for the Saturday.

THE fifth International Congress of Hygiene, which has concluded its session at the Hague, is reported to have been highly successful; it was decided to accept the invitation from Vienna for 1886.

IT is reported that Mr. Melville, chief engineer of the *Jeannette* Expedition, will command a Polar expedition which it is said will start next autumn to attempt to reach the Pole *viâ* Franz Josef Land. It is stated that Mr. Cyrus Field and the New York Yacht Club will each furnish one-half the cost of the expedition.

IN the course of the present month a geographical professorship will be established at each of the Russian universities. In Germany, fourteen out of twenty-one universities have a chair of this sort.

A VERY favourable Report has been issued of the second year of the College Hall of Residence for Women Students. That such an institution was wanted is shown by the fact that last autumn another house had to be added in order to meet the number of applications from students. The Hall is already almost self-supporting, and in another year will probably be entirely so; and it is hoped that this will encourage friends to assist the Committee in paying off the 1000*l.* they had to borrow in order to extend the premises. Subscriptions and donations may be sent to Mrs. Edward H. Busk, 44, Gordon Square, W.C.

THE Geographical Society have received a letter from Mr. H. H. Johnston, who has been sent out to explore and collect plants on Mount Kilimanjaro. It is dated June 18, from "Uvura, in Chagga, altitude 5000 feet." "For nearly a week now," Mr. Johnston says, "I have been settled on Kilimanjaro, camped on one of the loveliest sites in the world. Above me towers into the deep blue heaven the snowy head of Kibô, around me are green hills and forest-clad ravines in whose profound depths great cascades of water leap from rock to rock and splash the fronds of luxuriant ferns; before me lies spread out a vast blue plain—'all the world,' as my host, the chief Mandara, proudly says, and my view southward is only bounded by the distant horizon. Perched as I am up here on the shoulder of a great buttress of the mountain, I seem to be on a level with the uppermost flight of the vultures, who hardly ever soar higher, and who poise themselves and wheel in circles over the awful depths at my feet. When the first cares of my installation are over, I am going to set to work on a picture such as I see before me, and call the view 'à vol de vautour.'"

THE difference between the temperatures of places in America and those of places in similar latitudes in Europe is already well known, but it would hardly be expected to be so great as it actually was in January of this year. That month was a mild one all over Europe, but in the United States, especially in the eastern part, it was extremely cold. Thus, in Nashville and Knoxville, in the same latitude as Malta, the thermometer marked 26°·7 C. and 23°·3 C. of cold, while in Malta it was only 5°·9 below zero. At Indianapolis and Columbus it was 31°·7 C. and 28°·9 C. respectively below zero, while at Madrid, in the same latitude, the maximum was 9° below zero. The average temperature of the month in the States was 3° C. to 5° C. beyond the normal average.

THE experiment of MM. Renard and Krebs in balloon steering at Meudon, of which so much has recently been heard, formed the subject of a paper read before the Academy of Sciences on the 18th ultimo. The solution of the problem of aërial navigation was first attempted in 1855 by M. Giffard, who employed steam, then in 1872 by M. de Lôme, and finally by M. Tissandier, who was the first to apply electricity. The conditions which MM. Renard and Krebs studied to fulfil were steadiness of the path obtained by the shape of the balloon, and the arrangement of the rudder; the diminution of resistance while travelling by the proportion of the dimensions—bringing together the centres of traction and resistance; and finally, to attain a speed capable of resisting the winds prevailing in France during the greater part of the year. The paper then enters into details of the construction, and of the journey, during which the writers claim they were able to manœuvre the balloon as easily and effectively as a ship is put through its evolutions.

WE have recently received from various scientific societies in the United States their late publications. The contents of these

are too numerous and too varied to be noticed now in any but the most general way. The New York Academy of Sciences appears to lead them all in the number and importance of the papers read before it, in every conceivable department of science. The Philosophical Society of Washington sends us vol. vi. of its *Bulletin*, containing the President's address (on "The Three Methods of Evolution"), as well as the abstracts of a large number of papers. This Society appears to work in conjunction with the Smithsonian Institution. The last number of the *Bulletin* of the Buffalo Society of Natural Sciences is almost wholly occupied with an elaborate paper on the plants of Buffalo and its vicinity, by Mr. Day, the present instalment being occupied by the Cryptogams. The toilers in the vineyard of science in the United States are evidently numerous and enthusiastic, and they have provided themselves with ample means of giving their results to the world.

THE last numbers of the "Encyklopaedie der Naturwissenschaften" (Breslau, Eduard Trewendt) are Part 1, No. 37, and Part 2, Nos. 21 and 22. The first forms the continuation of the "Handworterbuch der Zoologie, Anthropologie, und Ethnologie," and numbers among its writers Shellwald, Reichenow, Pfeffer, Martens, Jager, Röckl, and others. Among the articles in the present instalment are the pacing of horses, by Prof. Röckl; the brain, by Mojisisowics; and on the geographical distribution of animals, by Dr. Reichenow. No. 21 of Part 2 continues the section on mineralogy, geology, and palæontology, and contains articles on islands, by Von Lasaulx; the Jura system, the formation of coal in the different geological epochs, and cryptogams, by Dr. Rolle. No. 22 belongs to the chemical section.

DURING the last fifty years several attempts have been made to form oyster banks in the Baltic. The first attempt was made about forty years ago, when a quantity of European oysters were laid down, but it proved a failure, and the oysters soon died. In recent years, however, experiments have been made with the American oyster (*Ostrea virginiana*), which, according to the researches of Prof. Möbius is a different variety of the European. The idea of laying down American oysters in the Little Belt was due to Mr. Meyer, an engineer of Hadersleben, who formed a company for the purpose of carrying it out, to which the Prussian Government granted a concession for forty years to form oyster banks up to lat. 55° N. In the autumn of 1879 Mr. Meyer went to the United States, whence he brought back to Hadersleben a million and a half small and half a million large oysters, which were laid down in ten different places from the Danish frontier to the southern part of the Als Sound. Recent examinations of these spots have shown varying results. In some there are only a few oysters left, and in others considerable quantities. Where seaweed is very plentiful the oysters have died. The best result was found on the south-east coast of Als. During the present summer fresh attempts at oyster-hatching are to be made in these parts, and the German Fishery Association has granted Prof. Möbius a sum of about fifty pounds towards expenses. On the west coast of Norway, too, strenuous efforts have been made in recent years to improve the oyster fisheries there, which were formerly very important. Several companies have been formed for acquiring old banks and restocking them. In some places the results have been very satisfactory.

THE Tung Wen, or Foreign Language College at Pekin, is about to issue a large work on Anatomy by Dr. Dudgeon of that place. It is said to contain prefaces, in the usual Oriental manner, from several of the highest officials at the capital. The work has over 500 cuts made at the Government expense. A large work on Physiology is also ready for the press; while Dr. Dudgeon has ready for the English press a little work on the diet, dress, and dwellings of the Chinese in relation to health.

IT is known that the Boyle-Marriott law is true only within certain limits, and that a gas submitted to great pressures, as well as to very low ones, ceases to obey it; the product received by multiplying its volume by its elasticity ceases to be a constant, and decreases under very low pressures: the elasticity decreases at a higher rate than the density of the gas, and to express the relations between the two, a more complicated formula must be resorted to. Another source of complication is due again to the condensation of the gases on the solid surfaces of the recipients, and if this cause be taken into account, the measured elasticities must be lower than the true ones, and in the rarefied gases the ratio between elasticity and density must increase with the increase of elasticity at a higher rate than would result from Prof. Mendeléeff's observations. Such was the idea that guided M. Kraevitch in a series of experiments he undertook a few years ago, with M. Petersen, in order to eliminate the influence of the condensation. These experiments being not sufficiently accurate, M. Kraevitch has now undertaken a new series of researches based on the rate of sound in different gases. They were carried on in tubes of very different lengths and diameters, and it appears from a preliminary communication, now published in the *Journal* of the Russian Chemical Society (vol. xvi. fasc. 6), that the air, when rarefied, does not obey at all the Boyle-Marriott law. The researches carried on on this principle promise to be, on the whole, very interesting, and may lead to conclusions of some value.

A SHOCK of earthquake occurred at Réunion on August 7 at midnight. The oscillation was from east to west, and was preceded by a loud report, like an explosion. No damage was done.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii* ♀) from South Africa, presented by Major Newson D. Garrick; a Moustache Monkey (*Cercopithecus cephus* ♂) from West Africa, presented by Mr. G. A. Broderick; a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mr. H. Johnson; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by the Rev. Walter Hudson; a Squirrel Monkey (*Chrysothrix sciurea*) from Brazil, presented by Mrs. J. M. A. King; a Himalayan Bear (*Ursus tibetanus*) from North India, presented by Mr. Percy H. Cooper; a Red and Yellow Macaw (*Ara chloroptera*) from South America, presented by Mr. P. J. Prior; a Common Cuckoo (*Cuculus canorus*), British, presented by Mrs. William Smith; a Sharp-nosed Crocodile (*Crocodilus acutus*) from Central America, a Hawk's-billed Turtle (*Chelone imbricata*) from the West Indies, presented by the Rev. W. T. Lax; two Spotted Slow-worms (*Acontias meleagris*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Common Slow-worm (*Anguis fragilis*), British, presented by Mr. H. Scherren; a Ludio Monkey (*Cercopithecus ludio*) from West Africa, a Kit Fox (*Canis velox*) from North America, a Banded Aracari (*Pteroglossus torquatus*) from Central America, an Æthiopian Wart Hog (*Phacochærus æthiopicus*) from South-East Africa, a Tiger Bittern (*Tigrisoma brasiliensis*) from Brazil, a Common Boa (*Boa constrictor*) from South America, an Indian Eryx (*Eryx johni*) from India, purchased.

OUR ASTRONOMICAL COLUMN

COMET 1884 *b*.—M. Trépied further writes with respect to his observations of the comet discovered by Mr. Barnard:—"I hope you will favourably receive some remarks on the subject of your last article on the Barnard Comet. You say that it would not be prudent to pronounce upon the nature of the orbit on account of the uncertainty which seems to attach to the observations at Algiers. There was in fact an error committed on the first day, in the identification of the star of comparison, but that error was rectified almost immediately, and I am able to state

that the verification to which I subsequently submitted that star (B.A.C. 5457) leaves no doubt as to the legitimacy of the identification. But I wish especially to remark that amongst the published orbits is one in which the observations at Algiers have had no part; it is that calculated by Chandler on the observations of July 16, 21, and 28." M. Trépied suggests that the conjecture of Prof. Weiss as to the nature of the orbit rested not only on the differences in the mean place, but on the agreement of his own elements with those of Chandler. We are now aware, however, as was mentioned last week, that the apparent deviation from parabolic motion was caused by error in the position published for the night of discovery, and that M. Trépied's observations (the comparison star having been identified) prove very exact. The doubt we expressed was occasioned by the large corrections given in the circular of the *Astronomische Nachrichten*.

BRORSEN'S COMET OF SHORT PERIOD.—The following positions of this comet are deduced upon the same assumption with respect to the epoch of perihelion passage as those lately given for the period of absence of moonlight in August:—

12h. G.M.T.		R.A. h. m.		Decl. ° ′		Distance from Earth		Sun
Sept. 15	...	10 26·6	...	+13 37	...	1·416	...	0·590
17	...	10 40·0	...	13 28	...	1·436	...	0·593
19	...	10 53·3	...	13 15	...	1·455	...	0·598
21	...	11 6·3	...	12 58	...	1·475	..	0·606
23	...	11 19·1	...	12 37	...	1·496	...	0·617
25	...	11 31·7	...	+12 12	..	1·518	...	0·630

An acceleration of four days in the time of arrival at perihelion would cause the following differences in the comet's geocentric position:—

On Sept. 15	...	In R.A.	+16·9 m.	...	In Decl.	+31
,, 23	...	,,	+15·3	...	,,	+ 1

The intensity of light on September 15 is 1·43, and the comet would rise about 2h. 8m. before the sun. It should be sought for as soon as the moon is off the morning sky.

M. Trépied writes on August 26 that he had commenced a search for the comet according to the places given in NATURE. "Malheureusement," he says, "à Algers le temps qui peut être consacré à la recherche est très-court, car le crépuscule arrive presque immédiatement. Néanmoins je n'ai pas encore perdu tout espoir."

THE CAPE HELIOMETER.—The Treasury have granted Dr. Gill's application for a heliometer of large size for the Royal Observatory at the Cape of Good Hope, and a contract has been entered into with the Messrs. Repsold of Hamburg. The instrument will be of seven inches aperture, and is to be completed by the end of 1886, at an expense of 2700*l*.

SCIENTIFIC SERIALS

The American Journal of Science, August 1884.—Contributions to meteorology: reduction of barometric observations to sea-level (continued), by Prof. Elias Loomis. The author considers that it is quite useless to seek for a formula exactly representing the barometric reduction to sea-level at all pressures and temperatures, unless the irregular movements in the upper and lower strata of the atmosphere be taken into account. But these movements are greatly modified by the obstruction of the mountains upon which the observations are made, and therefore vary with the locality; hence he concludes that such an attempt seems a hopeless undertaking.—Notes on the rock and ore-deposits in the vicinity of Notre Dame Bay in Newfoundland, by I. E. Wadsworth. The districts examined were chiefly various points between Exploits Burnt Island and Betts Cove, which yielded basalt, diorite, porodite, andesite (?), porphyrite, and argillite, variously impregnated with chalcopyrite, malachite, and copper. But none of the ores were found associated with serpentine, which was nowhere seen except in small quantity at Betts Cove.—On the origin of bitumens, by S. F. Peckham. The author deals with the views of those who regard bitumens (asphalt, naphtha, petroleum, &c.) either as indigenous to the rocks in which they are found, as the product of chemical action, or as a distillate produced by natural causes. He is on the whole inclined to regard these substances as distillations from animal and vegetable organic remains, and argues that if they are the result of a purely chemical process we should not expect to find Palæozoic petroleums of a composition corresponding with the simple animal and vegetable organisms that flourished at that period, and Tertiary petroleums containing nitrogen unstable, and corresponding with the decomposition-products of more highly organised beings; but we should expect to find a general uniformity in the character of the substance wherever found all over the earth. On the other hand, if petroleum is the product of metamorphism, its formation is coexistent only with that of metamorphic action, which does not seem to have prevailed on a large scale during recent geological periods. Hence on this hypothesis its production must be considered as practically ended.—On the measurement of rapidly alternating electric currents with the galvanometer, by L. M. Cheesman.—Note on some specimens of nickel ore from Churchill County, Nevada, by Spencer B. Newberry. The analysis of these samples gave:—

NiO	... ...	33·71 per cent.
As_2O_5	... ...	36·44 ,,
H_2O	... ...	24·77 ,,

From the extraordinary purity and richness of these ores, the author considers it probable that the Nevada mines, which run 6000 feet north-east and south-west to the Carson Desert, will eventually become a chief source of the world's supply of this valuable metal.—On the formation of gorges and waterfalls, by W. Morris Davis. The author considers that, although the Colorado Cañon, the greatest gorge in the world, was formed by rapid downward erosion following the rapid elevation of the plateau, most falls and ravines result from the local displacement of streams by blockades of glacial drift, or by temporary obstruction from the glacial sheet itself.—On the influence of light on the electrical resistances of metals, by Arthur E. Bostwick. From a series of experiments with various metals, the author concludes that, if light causes any diminution in the electrical resistance of metals, it probably does not exceed a few thousandths of one per cent.—Note on the rare mineral vanadinite occurring in the Black Prince Mine, Pinal County, Arizona, by Francis Hayes Blake.—Remarks on the united metatarsal bones of the Ceratosaurus, an already described new Dinosaurian, by Prof. O. C. Marsh. The author points out that all known adult birds, living and extinct, with perhaps the single exception of Archæopteryx, have the tarsal bones firmly united, whereas all the Dinosauria, except Ceratosaurus, have these bones separate. The exception in each case brings the two classes near together at this point, and their close affinity has now been clearly demonstrated.

Bulletin de l'Académie Royale de Belgique, May 1884.—Observations on the shooting-stars made at the Royal Observatory of Brussels on August 9-11, 1883, by L. Niesten.—Description of the effects of a stroke of lightning on the new Palace of Justice, Brussels.—Memoir on the process of segmentation in the Ascidians, and its relations with the organisation of the larvæ (two plates), by Edouard van Beneden and Charles Julin.—Some arithmetical theorems, by E. Catalan.—Researches on the absolute power of the muscles in the invertebrates, second part: absolute power of the flexor muscles of the pinchers in the decapod crustaceans (one plate), by Felix Plateau.—Exact dates of the birth and death of Wenceslas Coeberghér, by Auguste Castan.—Essay on freedom of conscience in Athens, by M. A. Wagener.—Theories of Plato and Aristotle on the social question, by Ch. Loomans.—Memoir on the best means of improving the moral, intellectual, and physical state of the working classes, by Joseph Danby.

SOCIETIES AND ACADEMIES

SYDNEY

Royal Society of New South Wales, July 2.—H. C. Russell, B.A., F.R.A.S., President, in the chair.—Six new members were elected, fifty-four donations received, and the following papers read:—Notes on gold, viz. (1) a remarkable occurrence of nearly pure gold in Queensland, being 99·7 of gold, the rest copper, with a trace of iron, found in quartz and stalactites of brown hæmatite; (2) preparation of pure gold; (3) volatilisation of gold, by A. Leibius, Ph.D., M.A.—Notes on minerals new to New South Wales, by Prof. Liversidge, F.R.S., accompanied by specimens. Remarkable concretions of friable iron pyrites containing septa of quartz, resembling in appearance the well-known "septaria" of the London Clay, large crystals of axinite, idocrase in association with grossularite from Nundle, tourmaline in large prisms resembling the celebrated Bovey Tracey forms, Scheelite, molybdenum ochre, antimonite containing native gold from near Armidale, and allophane, serving as a

matrix for native copper, Blayney.—On the oven-mounds of the aborigines in Victoria, by the Rev. Peter MacPherson, M.A. The situations, sizes, and structure (internal and external) of these aboriginal relics were considered, and measurements given. The cooking oven, or smaller portion of the mound, was specially investigated. Besides the more common contents, namely, ashes, charcoal, and stones, human remains were sometimes found. Where no timber existed, a kind of turf and coarse grass were used as fuel. Circles of stones girdling the mound were described. So far as appeared, no very high antiquity was required to account for the mounds.—Mr. W. Neill exhibited some very rich specimens of gold in quartz and mispickel from the new mine Wahaup, East Ballarat.

PARIS

Academy of Sciences, August 25.—M. Rolland, President, in the chair.—Remarks on aerial navigation, in connection with the experimental trip made on August 9 by Capts. Renard and Krebs with their new balloon, by M. Dupuy de Lome. The author regards the experiment as so far highly satisfactory, and announces that it will be soon renewed with a screw machine possessing double the motive power of the first, and calculated to travel in any direction with an average speed of fifteen miles an hour. It is further pointed out that the balloon is constructed on the principles expounded in a memoir addressed by the author to the Academy of Sciences and dated February 2, 1872.—Contributions to the study of algebraic equations: (1) general considerations, binomial and trinomial equations, by M. de Jonquières.—On the process of cold hammering, and the variation in the limit of elasticity in metals and other solid substances, by M. Tresca.—Researches in organic botany; studies on the formation and presence of nitrates in plants; methods of analysis, by MM. Berthelot and G. André. An account is here given of the authors' attempt at a complete analysis of a vegetable organism with a view to determining the chemical equation during its development from the fertilised germ to its fructification and reproduction. Experiments were also made for the purpose of varying the physiological conditions of vegetable growth, and for these various objects ten botanical species, including six varieties of the Amaranthus were subjected to a methodical and comparative study during the season of 1883.—Note on astronomical measurements and especially on the choice of a common meridian, by M. A. d'Abbadie. The author pronounces in favour of the west coast of Flores, one of the Azores, for the chief meridian, or else for its anti-meridian, should the latter be preferred. He also proposes the adoption of a unit of 10,000 kilometres for the measurement of celestial spaces, this unit to be called a *mégiste* (*μέγιστον*).—A study of the sphincters of the cardiac and other veins, with remarks on their hermetic occlusion during the presystole state, by M. P. Duroziez.—Note on the inequality in the distribution of the solar temperature according to latitude and the activity of the photosphere, by P. Lamey.—Observations of the new planet Palisa 239 made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—Observations of the Barnard comet and of the new planet Palisa 238, by M. Perrotin.—Remarks on the universal hour, and on the formula—

Universal time = local time − (12h. + longitude),

where the longitude is reckoned eastwards from 0h. to 24h., by M. Caspari.—Description of a thermo-regulator of simple construction intended also to serve as a registering thermometer (two illustrations), by M. E. H. von Baumhauer.—Researches on the infra-red spectra of emission of metallic vapours, by M. Henri Becquerel. The paper is accompanied by a table of the wave-lengths of the most intense rays, bands, or groups of rays characterising the spectra of the vapours of potassium, sodium, strontium, calcium, zinc, aluminium, cadmium, lead, silver, tin, and some other metals.—Determination of the indices of refraction by linear measurements, by M. Ch. V. Zenger.—On the quality of the various farinas obtained by different processes of grinding, by M. Aimé Girard.—Note on the poisonous properties of urea, determined by a series of experiments made on frogs, guinea-pigs, rabbits, and pigeons, by MM. Gréhant and Quinquaud. The experiments consisted in subcutaneous injections of aqueous solutions of pure urea, the doses being gradually increased, and invariably terminating in tetanic convulsions and death. The convulsions resembled those produced by strychnine, and were followed by death in the course of from one to ten hours.—Remarks on the action of high pressure on the phenomena of putrefaction and on the vitality of minute organisms in fresh and salt water, by M. A. Certes. The object of M. Certes' studies was to determine the processes and the conditions under which organic matter is reduced to the inorganic state at the bottom of the sea. Experiments were also incidentally made with the bacteria of charbon, which preserved their vitality and virulence under a pressure of 600 atmospheres, maintained for a period of twenty-four hours.—Remarks on the action of lesions of the rachidian bulb on the digestive functions, by MM. Couty, Guimaraes, and Niobey.—Experiments made to determine the loss of nitrogen during the fermentation of farmyard manure, by M. Ch. Brame.—On the dehiscence of the anthers in phanerogamous plants, by M. Leclerc du Sablon.—Report on the present state of the Krakatoa volcano, by MM. Bréon and Korthals. The report embodies an account not only of Krakatoa, but also of all the surrounding districts, which were wasted by the eruption of August 26, 1883. Some successful photographs were taken, including the only exact profiles hitherto obtained of Krakatoa.

VIENNA

Imperial Academy of Sciences, June 19.—R. Herth, researches on hemialbumose or propeptone.—R. Scharitzer, on the minerals and rocks of Jan Mayen.—F. Bayer, on the extremities of a young Hætteria.—K. Natterer, on the opposition of hydric chloride to dichlorocrotonaldehyde.—L. Tausch, on some Conchylia from the fauna of Lake Tanganyika (Central Africa), and their allied fossils.

July 3.—E. Marenzeller, on Southern Japanese Annelids; description of species of the genera Ampharetea, Terebellacea, Subellacea, and Serpulacea.—F. Bertolasi, on the applicability of Wittstein's and Kinkelin's formulæ to volumetric calculations.—S. Bernheimer, contribution to a knowledge of the nerve-fibre layer of the human retina.—A. Nalepa, preliminary communication on the anatomy of Tyroglypha.—T. Habermann, on acetonhydroquinone.—T. Zehenter, on the action of phenol and sulphuric acid on hippuric acid.—E. von Oppolzer, determination of the length of the pendulum at the Vienna Observatory.—M. Pernter, contribuions to a knowledge of the winds in the upper strata of the air.

July 10.—T. Lerch, researches on chelidonic acid.—A. Lieben and A. Haitinger, on chelidonic acid.—F. Spitzer and T. Kachler, on camphoronic acid.—H. Molisch, on aerotropism of roots.—T. von Oppolzer, determination of the force of gravity while using two Repsold's pendulums of different weights.

DESCRIPTIVE MINERALOGY

Text-Book of Descriptive Mineralogy. By Hilary Bauerman, F.G.S. 8vo; pp. vi. 399; 237 figures. (London: Longmans, Green, and Co., 1884.)

THIS is the companion volume to the "Systematic Mineralogy," by the same author, published in 1881. As far as space admits Mr. Bauerman endeavours to describe all the more important mineral species. His remarks about the names of minerals and their derivations are well chosen; and both mining students and teachers of mineralogy should note the following paragraph:—"In the case of minerals worked as metallic ores, the ordinary commercial names should always be used where possible. Thus for all purposes copper pyrites, tinstone, and zinc blende are preferable to chalcopyrite, cassiterite, and sphalerite."

The classification adopted by the author "is in the main similar to that of Rammelsberg's 'Mineral-Chemie.'" Each description gives the form, the structure, the composition, and chemical characteristics, and concludes with the occurrence and distribution of the mineral. The crystallographic form is indicated both by Miller's notation and that of Naumann; and the figures of crystals are from the excellent wood blocks used originally for Brooke and Miller's "Mineralogy."

As might be expected from the author's wide experience as a traveller, the parts relating to occurrence are generally quite as complete as is compatible with the size of the volume; but strange to say, under the head of copper pyrites, the author omits all mention of the great mines of the provinces of Huelva in Spain, and Alemtejo in Portugal. It is true that they are not forgotten by him when speaking of iron pyrites; but Rio Tinto, which produces more copper than any other mine in the world, surely deserves notice quite as much as Devon Great Consols, Mellanear, or South Caradon. We must here correct an error of the author, who places Buitron in Portugal, whereas it is in Spain; and the great Portuguese mine is at San Domingos, not at Pomaron, which is simply the port of shipment, about eleven miles from the actual workings.

The author's acquaintance with Cornwall is not so exact as might be expected, for we find him making the statement that "in Cornwall" the tourmaline "is almost invariably known by the old German miners' name of *Schorl*"; in reality the Cornish term is *Cockle*. Fluor is omitted from the list of minerals associated with tinstone, and it is by no means so certain, as the author thinks, that kaolin has been produced by the action of atmospheric agencies upon the felspars of granite. There is, on the contrary, much to be said for the theory that the decomposing agents came from below. The remark that copper pyrites has been found in Dolcoath and neighbouring mines "in zones alternating in depth with tin ore," would lead one to suppose that there were several copper ore zones in the mines, which is not the case. The published section of Dolcoath shows only one copper zone, including, roughly speaking, the upper half of the workings, and one tin zone, comprising the lower half. No doubt tin ore was obtained also from the *gossan* or ferruginous capping of the vein, and it might therefore be said that there were two tin zones with an intermediate copper zone, but this is not what is stated by the author. Under pyrites we read:—"In Cornwall the common term is Mundick, the varieties being distinguished as sulphur, copper, or arsenical mundic, according to the prevailing constituents." Does the author mean by this that a Cornish miner would call copper pyrites "copper mundic"? If so, he is surely mistaken.

We regret that there are occasional errors of spelling in the names of minerals and places. Thus "Freieslebenite" appears several times without the second "e," though it stands correct in the Index, and "Meconite" might puzzle the novice who had never heard of Meionite. However these are slight blemishes, and both they and the few other mistakes can easily be corrected in a second edition, which no doubt will be required, as Mr. Bauerman's manual is clear, compact, and handy, and is likely to be a favourite with students of mineralogy.

THE MOSSES OF NORTH AMERICA

Manual of the Mosses of North America. By Leo Lesquereux and Thos. James. 8vo, pp. 447, with Six Plates Illustrative of the Genera. (Boston: S. E. Cassino and Co.; London: Trübner and Co. 1884.)

WE have much pleasure in calling the attention of bryologists on this side of the Atlantic to this excellent handbook of the "Mosses of North America." Many contributors have aided in its preparation, and a series of unfortunate disasters have delayed its publication at least ten years beyond what was expected, a delay which, however, has brought with it the compensation of greater completeness. Its foundation was laid by W. S. Sullivant, who contributed to the first edition of Gray's "Manual of the Plants of the Northern United States" in 1848 a synopsis of the mosses then known within the same territory, which were not more than about 200 species. In the second edition of the "Manual," published in 1856, the number of species was doubled, and five plates were given to show the essential characters of the genera. Of both these two treatises a few separate copies were also struck off. At that time there were four excellent bryologists resident in the country who were working actively—Sullivant, Lesquereux, Austin, and James—so that rapid progress was made. When the third edition of the "Manual" was issued, it was planned that Sullivant, in cooperation with Lesquereux, who worked at mosses with Schimper before he emigrated to America, where he has done such excellent work in fossil botany, should undertake an improved handbook of the mosses as a separate publication. Sullivant died in the spring of 1873 without this being carried into effect. His collection of specimens, drawings, and manuscript notes was bequeathed to the herbarium of Harvard University, which under the charge of Prof. Gray has for many years been the main centre for botanical work in the United States. It was planned that Mr. T. P. James, who belonged to Philadelphia, but who removed to live at Cam-

bridge, and who was excellently qualified for the task, should take Sullivant's place in the undertaking, but he died in 1882, and Lesquereux, in old age with his sight failing, was again left alone. The book might have altogether collapsed if it had not been for the kind intervention of Dr. Sereno Watson, who now has charge of the Harvard Herbarium, and who, although not specially a bryologist, has taken upon himself the needful critical and editorial labour that was required to complete it.

The book as now published includes all the mosses which are known on the North American continent within the limits of the United States and northwards. There is already a "Manual of the Mosses of Tropical America," by Mitten, in the twelfth volume of the *Journal* of the Linnean Society, and there are special monographs by Bescherelle on the mosses of Mexico and the West Indies. Sullivant has published figures of most of the endemic types, and Drummond, Austin and Sullivant and Lesquereux have issued extensive sets of dried specimens with numbers and printed labels. In the present work 900 species are included. A very large proportion of them are European, and as the close identity of the moss-flora of the temperate zone in the two continents is so interesting and important from a geographical point of view, we should have been glad if the example of Dr. Gray in marking those species which are common to Europe and America had been followed. Of the six plates five are those which were sketched out by Sullivant, and the sixth is devoted mainly to the sections of Hypnum. The classification does not differ materially from that of Bruch and Schimper, familiar to us in England from being used in Wilson's "Bryologia." The definitions of species and genera are commendably full and clear, and in not establishing or admitting species upon a slender foundation of differential character, the authors have followed the excellent example that has made Dr. Gray's manual, which has now reached its fifth edition, one of the most popular and practically useful of botanical handbooks.

At the end there is a useful glossary of the technical terms used in the descriptions. As it is such a good and cheap book and includes such a large proportion of the British species, it is well worthy of the attention of our home collectors.

J. G. BAKER

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Diffusion of Species

DURING a recent cruise among the Hebrides two circumstances came before me, both of which are of some interest in natural history—one of them illustrating the curious conditions attending the diffusion of species, and the other illustrating the not less curious conditions affecting the multiplication of particular species in particular seasons.

The celebrated Island of Iona is separated from the nearest part of the Isle of Mull by a sound which is three-quarters of a mile wide. It is the channel of very strong tidal currents, and when the winds blow in certain directions a heavy sea runs through it. This sound has been an effectual isolater of Iona from the access of several species common in Mull. Among others are to be numbered snakes and other reptiles. Tradition ascribes the immunity of the sacred isle to the blessing of St. Columba. Certainly it has been complete. Yet, strange to say, this immunity has been this year endangered. During the late very hot August an adder attempted the passage to Iona, and was in the act of effecting a successful landing, when, fortunately, it was seen by a boy and a girl who were occupied among the stones on the sea-shore. The adder was tired by its long swim, and the boy killed it without difficulty by stamping on its head. This is surely a very curious case of migration; and it is difficult to conceive the impulse under which the snake committed itself to the tides and currents of a channel so broad and dangerous. The hot weather of this year has no doubt developed in all reptiles an abnormal activity; and I saw a youth in Mull who had recently very nearly lost his life from the bite of an adder. The description given me of his condition for many hours brought home to my mind almost for the first time that we have in our own island a veritable member of the terrible "Thanatophidia." But it seems quite unaccountable why such a reptile should have attempted to cross the Sound of Iona.

The other circumstance to which I have referred is the marvellous development of the Salpidæ this year in the Hebridean seas. I have cruised on those seas every year for fifteen years regularly, and I have been often on the look-out for these curious organisms; yet I have never seen them at all except once, and then only rarely and locally. Whereas this year the water was laden with them almost everywhere, and in some places it was rendered almost foul with their enormous quantity. In the Sound of Iona my tow-net was soon half filled with them; and the long chains of beautiful pattern which passed under the yacht lent an additional charm to the exquisite colour of that pure oceanic water. In the Sound of Raasay, near Portree, the number was still greater. But the maximum development appeared in Loch Scavaig, where, as far down as the eye could reach, there was nothing to be seen but Salpæ in every variety of concatenation and decatenation—long chains, short chains, and countless myriads of separated individuals—making the whole sea little more than a thick soup of Salpæ.

On being placed in a glass of water the muscular contractions of their bodies were beautifully exhibited, and their darting movements were very striking. Their exquisite crystalline material allowed every detail of structure to be seen; and on being placed in numbers in a bucket of water, and on being stirred at night, their phosphorescence was brilliant.

I should be glad to know from any of your correspondents whether there is any explanation of this exceptional development of these creatures.

ARGYLL

Inveraray, September 6

Meteor- Moon- and Sun-Shine

DESCENDING the Calton Hill from the Royal Observatory on Tuesday night, I was much struck with the appearance, though momentary only, of a fine meteor of Venus-like brightness, passing in a short course from south-east to north-east nearly horizontally, and at a height of about half a degree above the Pleiades, at 3 minutes past 12 G.M.T. The yellowness of the meteor's light was very conspicuous, contrasted with the blueness of the faint stars and of the sky about them in that direction, shimmering in pale blue reflected moonlight; and seemed to speak of abundance of sodium, as well as a low temperature of incandescence, in that particular meteor.

But very different was the colour in the opposite quarter of the sky, or just west of south, where the moon, within a day of the full, was shining brilliantly, in white light immediately around and above it, but producing between it and the horizon, and for a considerable distance on either side, exactly and most perceptibly that faintly claret-coloured haze, which I have been remarking about and beneath the sun all this year. Precisely too as with the sun, the colour was shown on this occasion with the moon to be in the very highest regions of the atmosphere by any cumulus clouds, at heights of 3000 or 4000 feet, that floated past, being pre-eminent on that warm-coloured backing, by the pearly whiteness of their lights and blueness of their shadows. Also so far quite agreeably with Mr. Backhouse's recent and very interesting letter in NATURE (p. 359), stating that he had

found a solar dust-halo, with effects like the above, more and more visible the higher he ascended amongst the Alps.

That such appearances were produced by solid particles in a cold state, and not by any new gas introduced into the atmosphere, seems to be borne out by three sets of rather extensive solar spectroscopings which I have lately carried out; for while there does not seem to be a single new line amongst the thousands of old ones, so far as I have yet examined the observations, there is only too abundant evidence of a continued dulling of the light of the sun's continuous spectrum all along its range.

This effect is of course more conspicuous in the faint regions at either end than in the bright middle, and would appear to be testified to undeniably by the following differential observation, viz. that with a prismatic apparatus, wherewith I could see lines in the bright regions, say of B, C, and D, rather better than I could with somewhat similar, but darker, prisms in 1877,—I could not see Brewster's line Y and its companion groups in the very faint ultra-red so well as I did then; and could not see the further-away line X at all, though in 1877 it was not only clear enough, but far fainter lines on either side of it were visible and micrometrically measurable. Neither in 1884 have I been able with the same eye and instrument to see anything at the violet end of the spectrum of the grand banded lines H and K, though they formed a daily subject of observation in 1877.

In 1856 I remarkably appreciated that an ascent to 11,000 feet of altitude on the Peak of Teneriffe enabled H and K to be seen with peculiar distinctness and fine resolution of much of their haze at lower levels into sharp lines; but would that have been equally the case this year, when the inhabited regions of the earth, and the lower clouds too, are covered in by a wide-spread blanket of dust in most anomalous extent and density?

Pons' Comet—Pink Glow

THIS comet was visible here up to the beginning of June. I saw it on fourteen nights in April and eighteen in May, including the last eleven nights of the latter month. It could be seen with an opera-glass up to April 3; my last sight of it was with a 4-inch telescope on June 1, or rather at 12.30 a.m. of June 2 (= June 1d. 1h. G.M.T.). On April 24, and again and particularly on May 24 it seemed to me to have become suddenly fainter, though there seemed nothing in the state of the sky to account for it; indeed, on the last-named night I have noted, "sky very clear." Up to at least May 28 its motion in two or three hours could be plainly seen. On that night, though "very diffused and faint," it was visible before the moon had set. It had not, I think, on June 2 reached the *minimum visibile*, but as I had no ephemeris subsequent to that (to the middle of April) given in NATURE, it would have been quite useless to have looked for it again after the moon had passed.

I may add that the "pink glows" have not yet left us; on the last two evenings (July 1 and 2), which were clear, they were very distinct.

A. S. ATKINSON

Nelson, N.Z., July 3

Alternation of Generations in Salpa

WHILE we are indebted to Prof. W. K. Brooks for having enunciated his views on this subject clearly in NATURE for August 14 (p. 367), I should like to point out that the misquotations which he has called attention to in an article of mine published in May (p. 67) do not invalidate the strength of the counter-arguments, although I must apologise for their having been allowed to appear.

He does not acknowledge that the question at issue is one not of fact but of the explanation of accepted fact, *i.e.* it is a question of theory. Undoubtedly an egg migrates from the body of the solitary Salpa to that of the chain form, but Kowalevsky, who himself describes this, does not agree with Prof. Brooks' conclusion drawn therefrom.

Prof. Brooks pointed out at greater length than I did that the [illegible] hermaphrodi[illegible] productive cell becomes marked out earlier and earlier, until in Salpa it is fully developed in the body of the gemmating individual. Then, instead of showing by his nomenclature that Salpa is the end of a series, he prefers to break loose from any attempt at continuity and to call the solitary Salpa a true female.

I, however, prefer to follow in the steps of Prof. Moseley, who says of similar changes in the Hydromedusæ, that "it would lead to great confusion if the old way of regarding the matter was upset. The past history of the gonophores must be taken into account, and the fact that the sexual elements, though now developed at a greater or less distance in many species, formerly undoubtedly originated within the gonophore."

As Prof. Brooks does not use language in this way, it is not remarkable that he criticises me for using the term "hydroid" in regard to Cunina at a stage *comparable* to the hydriform and gemmating person of a Sertularian, although I pointed out that it is a Medusa in both generations.

The fault of Prof. Brooks' argument is that he is not consistent. He says: "Very many chain Salpæ are produced at one time. As these have no power to reproduce by budding, they have *lost their ovaries*, although each of them when it is born contains, like the bud of Pyrosoma, a single unfertilised egg."

If this means that the egg is the sole remnant of the ovary, it admits all that I contend for; but if, on the other hand, it means that in a less modified condition these must have an ovary proper to the bud as well as the ovum received from the litary Salpa, it follows that Salpa cannot be differentiated from a form like Pyrosoma, where there is, so to speak, a migrating ovary, but no trace of ovary independently formed in the bud. The second ovary described by Salensky cannot be a trace of this, for it is simply another ovum with follicular covering precisely like the first.

R. N. GOODMAN

St. John's College, Cambridge

Forked Lightning

BY papers received by last mail I see that Mr. W. C. Gurley claims to have shown, by photographing a flash of lighthing, that the ordinary notion of *forked* lightning must be given up. I do not know whether this conclusion has been drawn from the photograph of a single flash or not, but you will see from the inclosed photographs that the conclusion is an entirely false one. An examination of my photographs will show that all the flashes except one had the zigzag form, and that some of them are magnificently forked. They resemble very closely the photographs of sparks from a Holtz electrical machine, taken by Mr. A. Matheson in Prof. Tait's laboratory, and published in vol. xxvii. Part 3, of the *Transactions* of the Royal Society of Edinburgh. The amount of detail shown in the photograph of the tree illuminated by the flash gives one a very good idea of the brightness, when we consider that exposure cannot have exceeded the millionth part of a second. I may add that my first photograph was taken on October 16, 1883, and was circulated amongst friends immediately afterwards.

C. MICHIE SMITH

Madras Christian College, Madras, August 9

Sun-Glows

AS one of the first to draw attention in the *St. James's Gazette* of October 1, and November 9, 1883, and many subsequent occasions, to those strange phenomena about the sun last autumn, will you kindly allow me space in your valuable columns to ask how it is possible to refer such effects any longer (as Mr. Backhouse does in your paper of August 14, p. 359) to volcanic dust from, I presume, the Krakatoa eruption, when we know now that in south latitudes these phenomena were observed by Mr. Neison of the Natal Observatory as early as the spring of 1883? He says that "they increased in intensity from February until June, when they were strongly marked." I have watched the sky as an artist (out of London) for quite forty years, and feel sure that this corona, or blanching of the sun, has been a more persistent feature of late years than formerly. It is still there, and may be seen without leaving England, or even London in clear weather, by looking for it from about an hour to half an hour before or after sunset and sunrise. The last very mild winter and the preceding one could have had no connection with the Krakatoa eruption, and I think that we must now seek for an explanation of the present and past atmospheric phenomena in some increase of solar energy, and consequent lifting of vapour higher than usual.

ROBERT LESLIE

6, Moira Place, Southampton, August 24

Fireballs

In addition to the occurrences recently recorded in your columns, it may be well to quote a further observation communicated in a letter, by Lady Borthwick, to the *Morning Post* for August 16, dated from Derculich, Ballinlaig, Perthshire, from which I extract the following particulars:—

As several curious phenomena of a like kind had been described as having occurred in Edinburgh during a terrific thunderstorm on Tuesday, August 12, the writer proceeds to detail what had been witnessed by herself and some others in her neighbourhood. The storm began at 10 o'clock in the morning and continued with unabated violence till past 10 at night. It appeared to be at its height from about 3 till 7 p.m., when as many as three flashes of lightning occurred to one peal of thunder. In many cases they were of a vivid pink colour. At about 6 o'clock a loud noise was heard, unlike any preceding it: "the heavens seemed to open, and there issued from the clouds what appeared like a ball of fire, about the size of a man's head, which exploded with a terrific crash, emitting quantities of sparks." It then appeared to descend at a distance of not more than twenty yards from the house. Mr. J. K. Laughton, commenting upon the phenomenon in the next issue, states that "ball lightning" is not solid, but yet in "passing along the surface of soft land it ploughs it up in a way that no cannon ball could do," and refers to an instance of this mentioned by Scott in his "Elementary Meteorology."

At a recent meeting of the Paris Academy of Sciences, M. Gaston Planté illustrated some remarks upon globular electric bolts by producing artificially effects analogous to those of fireballs, and it would be interesting to know more respecting their nature. As they appear to occur only very occasionally, on account of the rare conditions of the atmosphere producing them, it is certainly advisable to collect all the evidence respecting them that is obtainable. By such means it may in the course of time become possible for those who are competent to deal with the facts, to arrive at some definite conclusions concerning this little understood phenomenon. Wm. White

Deep-Sea Corals

Prof. H. N. Moseley, F.R.S., in his masterly address to the Biological Section of the British Association at Montreal, dealt, amongst other matters, with the zoological position of the remarkable genera of deep-sea corals named *Guynia*, *nobis*, and *Haplophyllia* and *Duncania*, of Pourtalès. He states that he has found, after examing sections of the last-named genus, that the soft parts indicate that it and the others are *Hexactinia*, and have the construction of *Caryophyllia* and of all other corals of that group. These genera were placed amongst the Rugosa, the first-mentioned by myself fourteen years since, and the others by Pourtalès later on. On April 3 of the present year I read a communication to the Linnean Society, entitled "A Revision of the Families and Genera of the Madreporaria," and this revision is published. As Prof. Moseley left England before I could send him a copy, he and some other naturalists who study the corals will be perhaps interested by knowing that I have placed those genera where Prof. Moseley has located them subsequently. They form an alliance in the family Turbinolidæ, and I was led to alter the classificatory position on account of a careful examination of the hard parts.

Iridescent Lunar Halos

On the evening of July 4, from 5.30 p.m. to 7 p.m., the moon, eleven days old, was surrounded with a series of extraordinary halos consisting of a succession of concentric rings; fine, clear starlight; very light airs from south-west and west-south-west; thermometer, 42°.

At 5.30, very light fleecy scud from south-west, the moon surrounded with a halo of about three times its diameter, of dullish white within a ring of orange; rapid changes ensued: the moon appeared within an opaque circle intensely white, surrounded with chromatic rings in the following order—yellow, orange, red, indigo, a broad ring of blue, yellow, orange, red, indigo, deep blue, bordered by a faint ring of orange. At this time the moon appeared as a bright boss on a many-coloured shield; changes rapidly followed: at 5.35 the rings were as follows—white, yellow, orange, red, indigo, blue, yellow, orange; for some moments the outer ring of orange became blurred, the broad ring of blue very deep and beautiful; at 5.50 all of the halo had disappeared; sky clear, bright starlight all round, except where a few light fleecy clouds lay to the north-east. At 6.10 light scud from south-west; at 6.12 halo again formed, as follows—white, yellow, orange; in a few moments were added red, indigo, blue, orange; soon a mass of whitish scud, light and fleecy, seemed to gather round the moon widely, in a huge irregular oval, changing almost to a circle with uneven edges. At 6.20 the halo had disappeared; then came a bow-shaped yellowish coloration on the south-west of the moon, changing instantly to orange, red, indigo, faint indistinct orange; at 6.22 all clear again; at 6.29 bright almost dazzling rays immediately surrounded or jettied from the moon. At 6.30, north of the moon, orange appeared on some light scud; soon changes again took place: immediately on the edge the moon, where the rays were so brilliant, was now very dark with jagged edges within an intensely white ring, surrounded with a series of sharply-defined chromatic rings in the order they appeared at 5.35. At 6.35 another mass of whitish scud widely surrounded the moon as before described; at 6.48 all clear again; instantly after an orange patch appeared on scud to the north; at 6.56 orange on east; at 7 p.m. all was again clear; rays as dazzling as at an earlier period; temperature sensibly lower; frost at night. Ohinitahi, N.Z., July 5

Sextants

In your review of the "Encyclopædia Britannia" published last week I notice that reference is made to an article on navigation by Capt. Moriarty, and attention is called to the very serious error in sextants arising from false centering. Having had some experience in the examination of these instruments, I can practically testify to this most important defect. Only a week or so since two sextants were received here for trial, one of which belonged to a captain of the mercantile marine. In both instances, although the mirrors and shades were good, yet the arc error due to false centering was excessively large, increasing from 0 at 0° to + 7′ at 60°, while at 90° it amounted to 10′. Surely this must be a serious matter to navigators, but, as you point out, for the small fee of five shillings persons ordering a sextant may direct the maker to send it to the Observatory, where suitable apparatus is arranged not only for examining the arc but also the mirrors and shades. It is only fair, however, to say that when instruments are sent direct from the makers we do not often have occasion to reject one. Indeed, superior sextants by first-class makers rarely have an error exceeding 1′ of arc, and often not more than 30″, but how few these are in comparison with the hundreds of inferior instruments that pass into the hands of the public without being tested. The Kew Observatory, Richmond, September 2

Electrical Rainbow

I was one of a deputation of River Tyne Commissioners who visited the South Foreland, to see the experimental lights now on trial there, on Saturday night, August 30. We were walking across the fields from the lights towards the observing hut No. 2, a distance of about a mile and a half. There was a fog more or less, and a shower of rain as we were approaching the hut, and every time the electric light from A tower revolved, a rainbow, very like a faint lunar bow, made its appearance. I could not see any prismatic colour, and the bow was only produced by the large electric light, with carbons of 1¾ inch in diameter. There was no bow visible from the old light, which has carbons of about ⅞ inch square, and none from either the gas or oil lights. I was informed that this was the first time such a phenomenon had been observed. R. S. Newall

Ferndene, September 3

Rainbow on Spray

A curious appearance, which I have never observed before, was visible here for a few minutes this forenoon. Large breakers were rolling in to the bay, and their fronts (covered with foam) were brilliantly white in the sunshine. But, as each passed a particular spot, directly opposite to the sun, the spray blown back from its crest took a bright reddish-brown colour. *This was the [illegible] of the primary rainbow.* When observed from a

more elevated point, the apparent colour of the spray became bluish. G. H.

September 5

Circular Rainbow seen from a Hill-top

NOTICING a communication in NATURE (p. 361) regarding the phenomenon of a circular rainbow, I thought it worth while to mention a case which lately came under my observation. Standing on a point of rock just opposite the beautiful falls of Montmorenci, Quebec, I was surprised to see a rainbow in the form of a circle passing through my feet. The spray from the falls was being blown into a deep cove in front of me, and the sun was high in the heavens behind. The primary was well defined and very beautiful; the secondary was faint. I understand that the conditions for seeing this circular rainbow are not often favourable at Montmorenci; still it may not be amiss to advise intending visitors *not* to stop at the bottom of the steps which lead down below the falls, but to clamber over the rocks as near the water as possible. W. L. GOODWIN

Montreal, August 28

Intelligence in Frogs

A FRIEND in Scotland has a small lake in his grounds, which are surrounded by a high wall. At the bottom of the lake is a sluice by which the water can be let off into a burn below the grounds. A few weeks ago the lady of the house was walking down the road outside the wall towards the burn when, to her astonishment, she met a multitude of frogs making their way up the road, which makes a considerable detour, to the gate leading into the grounds. On inquiry she found that the lake had that morning been emptied through the sluice, and it was plain that these were frogs which, having been carried down with the water to the burn, were now making their way back to their old home. By what instinct did they know that the long road led to the point from which the short one had started? B. W. S.

September 3

THE TEMPERATURE OF THE SOLAR SURFACE

THE power developed by the sun motor, recorded in NATURE, vol. xxix. p. 217, has established relations between diffusion and energy of solar radiation which prove that the temperature of the surface of the sun is extremely high. I have, therefore, during the summer solstice of 1884, carried out an experimental investigation for the purpose of demonstrating the temperature of the solar surface corresponding with the temperature transmitted to the sun motor. Referring to the illustrations previously published, it will be seen that the cylindrical heater of the sun motor, constructed solely for the purpose of generating steam or expanding air, is not well adapted for an exact determination of the amount of surface exposed to the action of the reflected solar rays. It will be perceived on inspection that only part of the bottom of the cylindrical heater of the motor is acted upon by the reflected rays, and that their density diminishes *gradually* towards the sides of the vessel; also that owing to the imperfections of the surface of the reflecting plates the exact course of the terminal rays cannot be defined. Consequently, the most important point in the investigation, namely, the area acted upon by the reflected radiant heat, cannot be accurately determined. I have accordingly constructed an instrument of large dimensions, a polygonal reflector (see Fig. 1), composed of a series of inclined mirrors, and provided with a central heater of conical form, acted upon by the reflected radiation in such a manner that each point of its surface receives an equal amount of radiant heat in a given time. The said reflector is contained within two regular polygonal planes twelve inches apart, each having ninety-six sides, the perimeter of the upper plane corresponding with a circle of eight feet diameter, that of the lower plane being six feet. The corresponding sides of these planes are connected by flat taper mirrors composed of thin glass silvered on the outside. When the reflector faces the sun at right angles, each mirror intercepts a pencil of rays of 32·61 square inches section, hence the entire reflecting surface receives the radiant heat of an annular sunbeam of $32·61 \times 96 = 3130$ square inches section. It should be observed that the area thus stated is 0·011 less than the total foreshortened superficies of the ninety-six mirrors if sufficiently wide to come in perfect contact at the vertices. Fig. 2 represents a transverse section of the instrument as it appears when facing the sun; the direct and reflected rays being indicated by dotted lines. The reflector and conical heater are sustained by a flat hub and eight radial spokes bent upwards towards the ends at an angle of 45°. The hub and spokes are supported by a vertical pivot, by means of which the operator is enabled to follow the diurnal motion of the sun, while a horizontal axle, secured to the upper end of the pivot, and held by appropriate bearings under the hub, enables him to regulate the inclination to correspond with the altitude of the luminary. The heater is composed of rolled plate iron 0·017 inch thick, and provided with head and bottom formed of non-conducting materials. By means of a screw-plug passing through the bottom and entering the face of the hub the heater may be applied and removed in the course of five minutes, an important fact, as will be seen hereafter. It is scarcely necessary to state that the proportion of the ends of the conical heater should correspond with the perimeters of the reflector, hence the diameter of the upper end, at the intersection of the polygonal plane, should be to that of the lower end as 8 to 6, in order that every part may be acted upon by reflected rays of equal density. This condition being fulfilled, the temperature communicated will be perfectly uniform. A short tube passes through the upper head of the heater, through which a thermometer is inserted for measuring the internal temperature. The stem being somewhat less than the bore of the tube, a small opening is formed by which the necessary equilibrium of pressure will be established with the external atmosphere. It should be mentioned that the indications of the thermometer during the experiment have been remarkably prompt, the bulb being subjected to the joint influence of radiation and convection.

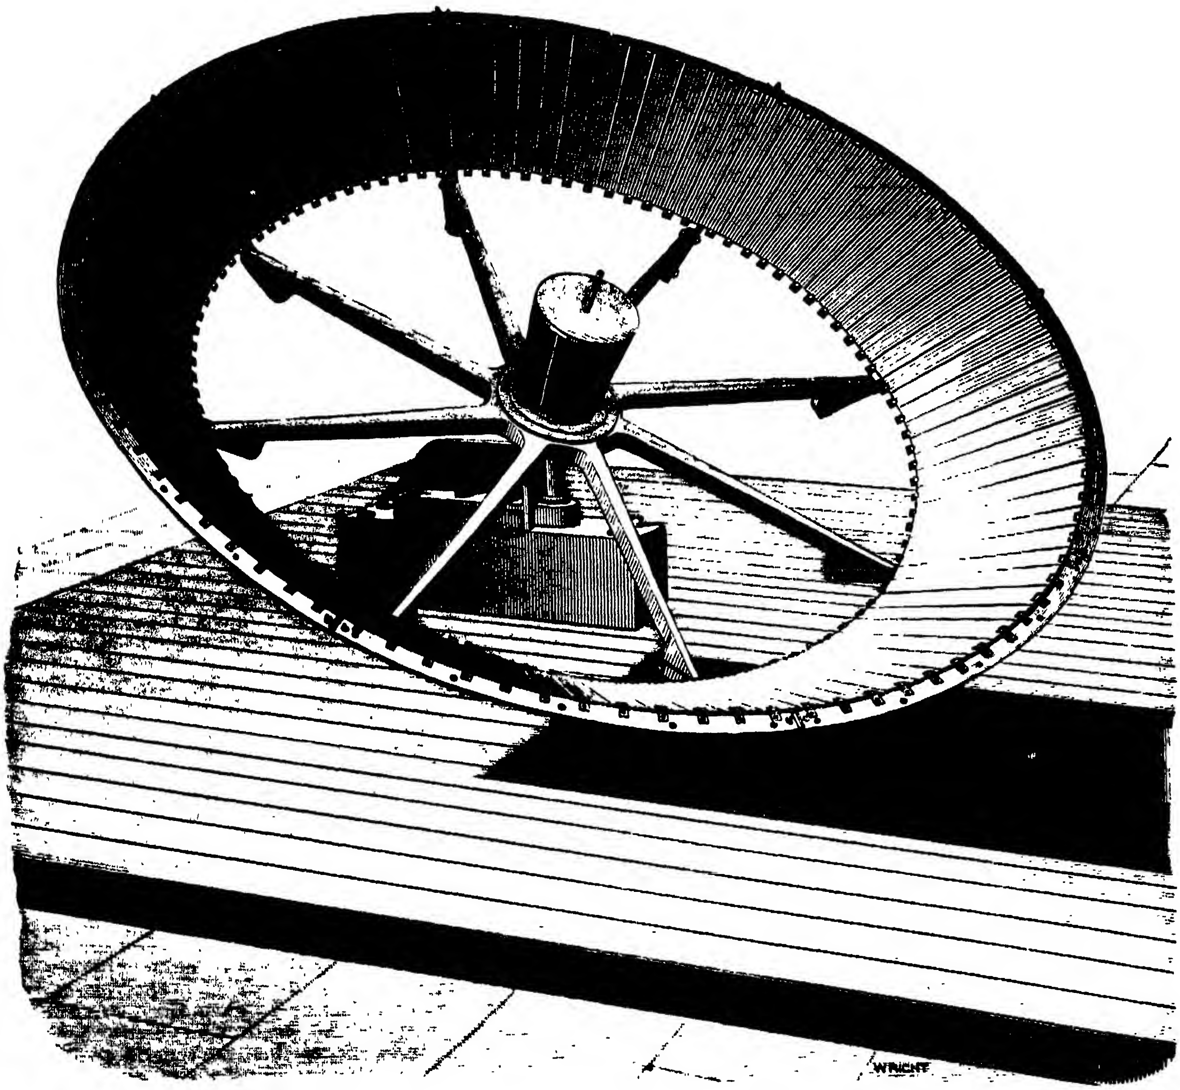
The foregoing particulars, it will be found, furnish all necessary data for determining with absolute precision the *diffusion* of rays acting on the central vessel of the solar pyrometer. But the determination of temperature which uninterrupted solar radiation is capable of transmitting to the polygonal reflector calls for a correct knowledge of atmospheric absorption. Besides, an accurate estimate of the loss of radiant heat attending the reflection of the rays by the mirrors is indispensable. Let us consider these points separately.

Atmospheric Absorption.—The principal object of conducting the investigation during the summer solstice has been the facilities afforded for determining atmospheric absorption, the sun's zenith distance at noon being only 17° 12′ at New York. The retardation of the sun's rays in passing through a clear atmosphere obviously depends on the depth penetrated; hence—neglecting the curvature of the atmospheric limit—the retardation will be as the secants of the zenith distances. Accordingly, an observation of the temperature produced by solar radiation at a zenith distance whose secant is *twice* that of the secant of 17° 12′, viz. 61° 28′, determines the minimum atmospheric absorption at New York. The result of observations conducted during a series of years shows that the maximum solar intensity at 17° 12′ reaches 66°·2 F., while at a zenith distance of 61° 28′ it is 52°·5 F.; hence, minimum atmospheric absorption at New York, during the summer solstice, is $66°·2 - 52°·5 = 13°·7$ F., or $\frac{13·7}{66·2} = 0·207$ of the sun's radiant energy where the rays enter the terrestrial atmosphere.

In order to determine the loss of energy attending the

reflection of the rays by the diagonal mirrors, I have constructed a special apparatus, which by means of a parallactic mechanism faces the sun at right angles during observations. It consists principally of two small mirrors, manufactured of the same materials as the reflector, placed diagonally at right angles to each other; a thermometer being applied between the two, whose stem points towards the sun. The direct solar rays entering through perforations of an appropriate shade, and reflected by the inclined mirrors, act simultaneously on opposite sides of the bulb. The mean result of repeated trials, all differing but slightly, show that the energy of the direct solar rays acting on the polygonal reflector is reduced 0·235 before reaching the heater.

In accordance with the previous article, the investigation has been based on the assumption that, *the temperatures produced by radiant heat at given distances from its source are inversely as the diffusion of the rays at those distances. In other words, the temperature produced by solar radiation is as the density of the rays.*



Captain Ericsson's Solar Pyrometer, erected at New York, 1884.

It will be remembered that Sir Isaac Newton, in estimating the temperature to which the comet of 1680 was subjected when nearest to the sun, based his calculations on the result of his practical observations that the maximum temperature produced by solar radiation was one-third of that of boiling water. Modern research shows that the observer of 1680 underrated solar intensity only 5° for the latitude of London. The distance of the comet from the centre of the sun being to the distance of the earth from the same as 6 to 1000, the author of the "Principia" asserted that the density of the rays was as 1000^2 to $6^2 = 28{,}000$ to 1: hence the comet was subjected to a temperature of $28{,}000 \times \frac{180^\circ}{3} = 1{,}680{,}000^\circ$, an intensity exactly "2000 times greater than that of red-hot iron" at a temperature of 840°. The distance of the comet from the solar surface being equal to one-third of the sun's radius, it will be seen that, in accordance with

the Newtonian doctrine, the temperature to which it was subjected indicated a solar intensity of $\frac{4^2 \times 1,680,000}{3^2} =$ 2,986,000° F.

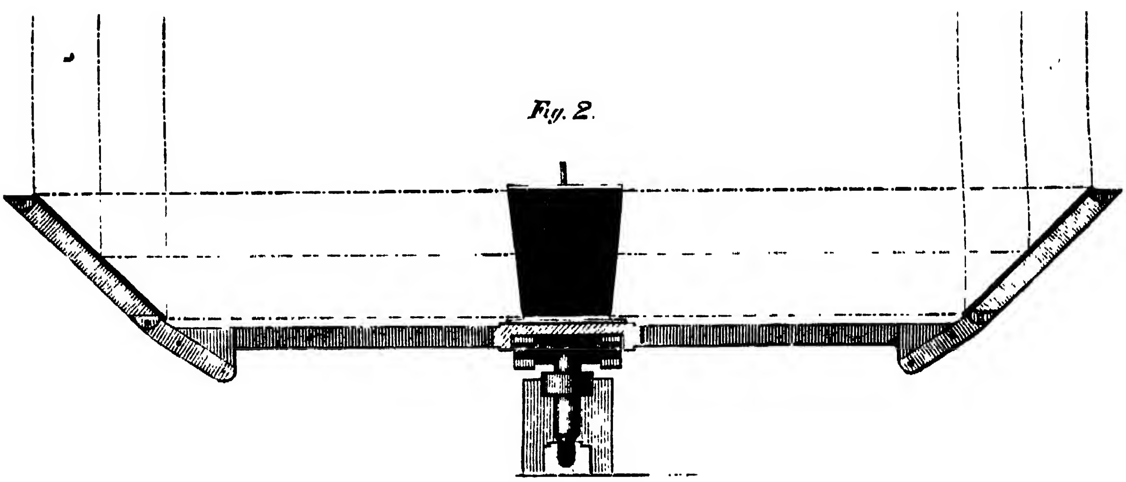
The writer has established the correctness of the assumption that "the temperature is as the density of the rays," by showing practically that the *diminution* of solar temperature (for corresponding zenith distances) when the earth is in aphelion corresponds with the increased diffusion of the rays consequent on increased distance from the sun. This practical demonstration, however, has been questioned on the insufficient ground that "the eccentricity of the earth's orbit is too small and the temperature produced by solar radiation too low" to furnish a safe basis for computations of solar temperature.

In order to meet the objection that the diffusion of the rays in aphelion do not differ sufficiently, the solar pyrometer has been so arranged that the density, *i.e.* the diffusion of the reflected rays, can be changed from a ratio of 1 in 5040 to that of 1 in 10,241. This has been effected by employing heaters respectively 10 inches and 20 inches in diameter. With reference to the "low" solar temperature pointed out, it will be perceived that the adopted expedient of increasing the density of the rays without raising the temperature by *converging* radiation, removes the objection urged.

Agreeably to the dimensions already specified, the area of the 10-inch heater acted upon by the reflected solar rays is 331·65 square inches, the area of the 20-inch heater being 673·9 square inches. The section of the annular sunbeam whose direct rays act upon the polygonal reflector is 3130 square inches, as before stated.

Regarding the diffusion of the solar rays during the investigation, the following demonstration will be readily understood. The area of a sphere whose radius is equal to the earth's distance from the sun in aphelion being to the sun's area as $218 \cdot 1^2$ to 1, while the reflector of the solar pyrometer intercepts a sunbeam of 3130 square inches section, it follows that the reflector will receive the radiant heat developed by $\frac{3130}{218 \cdot 1^2} = 0 \cdot 0658$ square inch of the solar surface. Hence, as the 10-inch heater presents an area of 331·65 square inches, we establish the fact that the reflected solar rays, acting on the same, are *diffused* in the ratio of 331·65 to 0·0658, or $\frac{331 \cdot 65}{0 \cdot 0658} = 5040$ to 1; the

Fig. 2.



diffusion of the rays acting on the 20 inch heater being as 673·9 to 0·0658, or $\frac{673 \cdot 9}{0 \cdot 0658} = 10,241$ to 1.

The atmospheric conditions having proved unfavourable during the investigation, maximum solar temperature was not recorded. Accordingly, the heaters of the solar pyrometer did not reach maximum temperature, the highest indication by the thermometer of the small heater being 336°·5, that of the large one being 200°·5 above the surrounding air. No compensation will, however, be introduced on account of deficient solar heat, the intention being to base the computation of solar emperature solely on the result of observations conducted at New York during the summer solstice of 1884. It will be noticed that the temperature of the large heater is proportionally higher than that of the small heater, a fact showing that the latter, owing to its higher temperature, loses more heat by radiation and convection than the former. Besides, the rate of cooling of heated bodies increases more rapidly than the augmentation of temperature.

The loss occasioned by the imperfect reflection of the mirrors, as before stated, is 0·235 of the energy transmitted by the direct solar rays acting on the polygonal reflector, hence the temperature which the solar rays are capable of imparting to the large heater will be 200°·5 × 1·235 = 247°·617; but the energy of the solar rays acting on the *reflector* is reduced 0·207 by atmospheric absorption, consequently the ultimate temperature which the sun's radiant energy is capable of imparting to the heater is 1·207 × 247°·617 = 298°·87 F. It is hardly necessary to observe that this temperature (developed by solar radiation diffused fully ten-thousandfold) must be regarded as an *actual* temperature, since a perfectly transparent atmosphere, and a reflector capable of transmitting the whole energy of the sun's rays to the heater, would produce the same.

The result of the experimental investigation carried out during the summer solstice of 1884 may be thus briefly stated. The diffusion of the solar rays acting on the 20-inch heater being in the ratio of 1 to 10,241, the temperature of the solar surface cannot be less than 298°·87 × 10,241 = 3,060,727° F. This underrated computation must be accepted unless it can be shown that the temperature produced by radiant heat is not inversely as the diffusion of the rays. Physicists who question the existence of such high solar temperature should bear in mind that in consequence of the great attraction of the solar mass, hydrogen on the sun's surface raised to a temperature of 4000° C., will be nearly twice as heavy as hydrogen on the surface of the earth at ordinary atmospheric temperatures; and that, owing to the immense depth of the solar atmosphere, its density would be so enormous at the stated

low temperature that the observed rapid movements within the solar envelope could not possibly take place. It scarcely needs demonstration to prove that extreme tenuity can alone account for the extraordinary velocities recorded by observers of solar phenomena. But *extreme tenuity* is incompatible with low temperature and the pressure produced by an atmospheric column probably exceeding 50,000 miles in height subjected to the sun's powerful attraction, diminished only one-fourth at the stated elevation. These facts warrant the conclusion that the high temperature established by our investigation is requisite to prevent undue density of the solar atmosphere.

It is not intended at present to discuss the necessity of tenuity with reference to the functions of the sun as a radiator; yet it will be proper to observe that on merely dynamical grounds the enormous density of the solar envelope which would result from low temperature, presents an unanswerable objection to the assumption of Pouillet, Vicaire, Sainte-Claire Deville, and other eminent *savants*, that the temperature of the solar surface does not reach 3000° C.

J. ERICSSON

THE BRITISH ASSOCIATION

HOSTS and guests have been abundantly satisfied with the results of the Canadian Meeting of the British Association. The Canadians have done their very utmost for their guests, and the latter appear to have responded heartily. There have been, to judge from the very full reports in the *Times*, some notable incidents in connection with the meeting, which will no doubt be fully noticed in the reports from our Special Correspondents, which we hope to receive in time for next week's number.

The General Committee met on Wednesday, with Lord Rayleigh in the chair. The aggregate membership was reported as 1773, of whom 558 were old and 1215 new. The following are the grants of money that have been made:—

Mathematical Section.—Meteorological observations near Chepstow, 25*l.*; synoptic charts of the Indian Ocean, 50*l.*; reduction of tidal observations, 10*l.*; calculation of mathematical tables, 100*l.*; meteorological observations on Ben Nevis, 50*l.*; solar radiation, 20*l.*; meteoric dust, 70*l.*

Chemical Section.—Vapour pressures and refractive indices of salt solutions, 25*l.*; chemical nomenclature, 5*l.*; physical constants of solutions, 20*l.*

Geological Section.—Volcanic phenomena of Vesuvius, 25*l.*; Raygill fissure, 15*l.*; earthquake phenomena of Japan, 75*l.*; fossil Phyllopoda of the Palæozoic rocks, 25*l.*; fossil plants of British Tertiary and Secondary beds, 50*l.*; *Geological Record*, 50*l.*; erosion of seacoasts, 10*l.*; circulation of underground waters, 10*l.*

Biological Section.—Table at Naples Zoological Station, 100*l.*; *Zoological Record*, 100*l.*; migration of birds, 30*l.*; exploring Kilimanjaro and adjoining mountains of Equatorial Africa, 25*l.*; recent Polyzoa, 10*l.*; marine biological station at Granton, 100*l.*; biological stations on coast of United Kingdom, 150*l.*

Geographical Section.—Exploring New Guinea, 200*l.*; exploring Mount Roraima, 100*l.*

Mechanical Section.—Patent legislation, 5*l.*

Anthropological Section.—Investigating the characteristic physical and other features of north-west tribes of Canada, 50*l.*; physical characteristics of the races in the British Isles, 10*l.* Total, 1525*l.*

In the case of the following Committees no money grants were voted:—Committees on practical standards for use in electrical measurements, for promoting tidal observations in Canada, for calculating tables of fundamental variations of algebraic forms, for securing harmonic analysis in reducing tidal observations, for comparing and reducing magnetic observations, for investigating the rate of increase of underground temperatures, for securing an international geological map of Europe, for reporting on erratic blocks of England, Wales, and Ireland, for examining marine life on coasts and rivers of North America, for survey of Palestine, and for science teaching in elementary schools. A vote was passed that the Council be recommended to request the Admiralty to adopt an harmonic analysis for the reduction of tidal observations. This is already being done in Germany, France, India, and elsewhere. A letter was read on the subject prepared by Sir William Thomson and Prof. G. H. Darwin to send to the Admiralty. The Council was also recommended to request the Canadian Government to adopt measures for investigating the physical character, languages, social and artistic condition of the native tribes of the Dominion. Various American members having suggested that an International Scientific Congress be formed, this subject was referred to the Committee by several Sections.

The General Committee adjourned to meet in London on November 11.

The closing meeting of the Association was held in Queen's Hall the same afternoon. There was a large attendance, Lord Rayleigh being in the chair. Admiral Ommanney, the acting treasurer, announced the membership, and also the total receipts, which have been about 1800*l.* The suggestion as to an International Scientific Congress was received with applause.

The Corporation and Faculty of McGill University were on the platform, and Sir William Dawson, the Principal, after a brief preliminary address, conferred the honorary degree of LL.D. upon the leading members of the Association, whose names have already been given. As the diplomas were delivered, warm applause greeted each recipient.

Lord Rayleigh thanked the University for the honours conferred and also for the splendid hospitality given to the Association, the recollection of which they would retain during the remainder of their lives. He said that no previous meeting had been so well provided with meeting-rooms as the University furnished. As a slight token of acknowledgment for Montreal's reception, the Association had provided a gold medal and endowment for McGill University, although he felt they could never fully appreciate the generosity of their hosts.

Sir Richard Temple moved, and Prof. Boyd Dawkins seconded, a resolution expressing cordial sympathy with the popular movement set on foot in Montreal to establish a public library worthy of the great city to properly mark the occasion of the first meeting of the British Association in Canada. Both made brief addresses, urging the members to aid the project. Sir William Thomson spoke in its advocacy, saying that a good library would be of vast importance to Montreal and to this portion of North America, that it would be an excellent basis for the subsequent establishment of a good scientific school. He urged the members to give liberal subscriptions. The resolution was adopted amid applause.

Sir Lyon Playfair moved, and General Lefroy seconded, a resolution of cordial thanks to the Dominion Government for the aid, support, and sympathy shown in promoting the Montreal meeting of the British Association, and for the warm interest felt in its success, which was adopted. Mr. J. White, a member of the Canadian House of Commons, responded for the Dominion Government.

Sir William Thomson moved, and Sir Frederick Bramwell seconded, a resolution of thanks to the McGill University, the Corporation of Montreal and its citizens, with a long list of other bodies who aided in promoting the objects of the meeting. Sir James Ferrier responded, saying, in the course of a felicitous address, that already the projected public library had been fairly started by a

proposed gift to McGill College for this purpose, by a benevolent gentleman of Montreal, of $50,000.

Other votes of thanks were passed to railway, steamer, and telegraph companies, and others who have aided the meeting. Mr. Hugh M'Lennan and Mr. Andrew Robertson responded for them.

The final vote of thanks to the President was moved by Prof. Daniel Wilson and seconded by Prof. Robert Ball and Sir William Dawson. After a brief appropriate reply by Lord Rayleigh, the British Association adjourned, to meet at Aberdeen in 1885.

About 300 British and Canadian members of the Association have arrived in Philadelphia from Montreal to attend the meetings of the American Association for the Advancement of Science. A local hospitality committee received them at the railway stations, providing homes for them with citizens or in hotels. They were formally welcomed to Philadelphia at a large meeting at the Academy of Music on Friday night. Mr. John Welsh, formerly Minister to England, delivered an address as chairman of the local committees, and Provost Pepper, of the University of Pennsylvania, made a special address of welcome, to which Prof. Robert S. Ball replied for the British Association. A members' promenade reception and banquet followed. The British guests were given excursions on Saturday to the Atlantic sea-coast resorts near Philadelphia; also by the Pennsylvania Railroad to Cresson, at the summit of the Alleghany Mountains; also by the Reading Railroad through the anthracite coal regions of Pennsylvania.

The American Association has appointed a Committee to confer with a similar Committee of the British Association relative to arranging for the proposed International Scientific Congress referred to in the closing proceedings of the British Association at Montreal.

SECTION E

GEOGRAPHY

OPENING ADDRESS BY GENERAL SIR J. H. LEFROY, R.A., C.B., K.C.M.G., F.R.S., F.S.A., V.P.R.G.S., PRESIDENT OF THE SECTION

MAN'S acquaintance with the planet he inhabits, with the earth which he is to replenish and to subdue, has been a thing of growth so slow, and is yet so imperfect, that we may look to a far distant day for an approach to a full knowledge of the marvels it offers, and the provision it contains for his well-being. He has seen, as we now generally believe, in silent operation, the balanced forces which have replaced the glacier by the forest and the field; which have carved out our present delights of hill and dale in many lands, and clothed them with beauty; and it may be that changes as great will pass over the face of the earth before the last page of its history is written in the books of eternity. But it is no longer before unobservant eyes that the procession of ages passes. Geography records the onward march of human families; often by names which survive them it rears enduring monuments to great discoverers, leaders, and sufferers; it is an indispensable minister to our every-day wants and inquiries; but beyond this it satisfies one of the most widely diffused and instinctive cravings of the human intelligence, one which from childhood to maturity, from maturity to old age, invests books of travels with an interest belonging to no other class of literature. If "the proper study of mankind is man," where else can we learn so much about him, or be presented with such perplexing problems, such diversity in unity, such almost incredible contrasts in the uses of that noble reason, that Godlike apprehension, which our great poet attributes to him? or see the "beauty of the world, the paragon of animals" (*Hamlet*, Act. ii. Sc. 2) in conditions so unlike his birthright? Geography, then, is far from being justly regarded as a dry record of details which we scarcely care to know, and of statistics which are often out of date.

It is scarcely necessary to do more than allude here to the intimate relations between geography and geology. The changes on the earth's surface effected within historical times by the operation of geological causes, and enumerated in geological books, are far more numerous and generally distributed than most persons are aware of; and they are by no means confined to sea-coasts, although the presence of a natural datum in the level of the sea makes them more observed there. A recent German writer, Dr. Hahn, has enumerated ninety-six more or less extensive tracts known to be rising or sinking. We owe to Mr. R. A. Peacock the accumulation of abundant evidence that the island of Jersey had no existence in Ptolemy's time, and probably was not wholly cut off from the Continent before the fourth or fifth century. Mr. A. Howarth has collected similar proofs as to the Arctic regions; and every fresh discovery adds to the number. Thus the gallant, ill-fated De Long, a name not to be mentioned without homage to heroic courage and almost superhuman endurance, found evidence that Bennett Island has risen a hundred feet in quite recent times. Nordenskjöld found the remains of whales, evidently killed by the early Dutch fishers, on elevated terraces of Martin's Island. The recent conclusion of Prof. Hull, that the land between Suez and the Bitter Lakes has risen since the Exodus, throws fresh light on the Mosaic account of that great event; and to go still further south, we learn from the Indian Survey that it is "almost certain" that the mean sea-level at Madras is a foot lower, *i.e.* the land a foot higher, than it was sixty years ago. If I do not refer to the changes on the west side of Hudson's Bay, for a distance of at least six hundred miles, it is only because I presume that the researches of Dr. Robert Bell are too well known here to require it. Any of my hearers who may have visited Bermuda are aware that so gently has that island subsided, that great hangings of stalactite, unbroken, may be found dipping many feet into the sea, or, at all events, into salt-water pools standing at the same level, and we have no reason to suppose the sinking to have come to an end. We learn from the Chinese annals that the so-called Hot Lake Issyk-kul, of Turkestan, was formed by some convulsion of nature about 160 years ago (*Proc. R.G.S.* vol. xviii. p. 250), and there seems no good reason to reject the Japanese legend that Fusiyama itself was suddenly thrown up in the third century before our era (B.C. 286). These are but illustrations of the assertion I began with, that geography and geology are very nearly connected, and it would be equally easy to show on how many points we touch the domain of botany and natural history. The flight of birds has often guided navigators to undiscovered lands. Nordenskjöld went so far as to infer the existence of "vast tracts, with high mountains, with valleys filled with glaciers, and with precipitous peaks," between Wrangel Land and the American shores of the Polar Sea, from no other sign than the multitudes of birds winging their way northward in the spring of 1879, from the *Vega*'s winter quarters. The walrus-hunters of Spitzbergen drew the same conclusion in a previous voyage from the flight of birds towards the Pole from the European side. Certainly no traveller in the more northern latitudes of this continent in the autumn, can fail to reflect on the ceaseless circulation of the tide of life in the beautiful harmony of Nature, where he finds that he can scarcely raise his eyes from his book at any moment, or direct them to any quarter of the heavens, without seeing countless numbers of wild fowl, guided by unerring instinct, directing their timely flight towards the milder climates of the South.

To address you on the subject of geography, and omit mention of the progress made within these very few years in our knowledge of the geography of this Dominion, might indeed appear an unaccountable, if not an unpardonable, oversight; nevertheless, I propose to touch upon it but briefly, for two reasons: first, I said nearly all I have to say upon a similar occasion four years ago; secondly and chiefly, because I hope that some of those adventurous and scientific travellers who have been engaged in pushing the explorations of the Geological Survey and of the Canada Pacific Railway into unknown regions will have reserved some communications for this Section. Canada comprises within its limits two spots of a physical interest not surpassed by any others on the globe. I mean the pole of vertical magnetic attraction, commonly called the magnetic pole; and the focus of greatest magnetic force, also often, but incorrectly, called a pole. The first of these, discovered by Ross in 1835, was revisited in May 1847 by officers of the Franklin Expedition, whose observations have perished, and was again reached or very nearly so by McClintock in 1859, and by Schwatka in 1879; neither of these explorers, however, was equipped for observation. The utmost interest attaches to the question whether the magnetic pole has shifted its position in fifty years, and although I am far from rating the difficulty lightly, it is probably approachable overland, without the great cost of an Arctic expedition. The

second has never been visited at all, although Dr. R. Bell, in his exploration of Lake Nipigon, was within 200 miles of it, and the distance is about the same from the Rat Portage. It is in the neighbourhood of Cat Lake. Here then we have objects worthy of a scientific ambition and of the energies of this young country, but requiring liberal expenditure and well-planned efforts, continued steadily, at least in the case of the first, for, perhaps, three or four years. Of objects more exclusively geographical, to which it may be hoped that this meeting may give a stimulus, I am inclined to give a prominent place to the exploration of that immense tract of seventy or eighty thousand square miles, lying east of the Athabasca River, which is still nearly a blank on our maps, and in connection with such future exploration I cannot omit to mention that monument of philological research, the "Dictionary of the Languages of the native Chipewyans, Hare Indians, and Loucheux," lately published by the Rev. E. Petitot. The lexicon is preceded by an introduction, giving the result of many years' study among these people of the legends or traditions by which they account for their own origin. M. Petitot, who formerly was unconvinced of their remote Asiatic parentage, now finds abundant proof of it. But perhaps his most interesting conclusion is that in these living languages of the extreme north, we have not only the language of the *Nabajos*, one of the Apache tribes of Mexico, which has been remarked as linguistically distinct from the others, but also the primitive Aztec tongue, closely resembling the language of the Incas, the Quichoa, still spoken in South America. I need not say how greatly these relations, if sustained by the conclusions of other students, are calculated to throw light upon the profoundly interesting question of the peopling of America.

This is perhaps a proper occasion to allude to a novel theory proposed about two years ago, with high official countenance, upon a subject which will never cease to have interest, and perhaps never be placed quite beyond dispute. I mean the landfall, as it is technically called, of Columbus, in 1492. The late Captain G. V. Fox, of the Admiralty, Washington, argued in a carefully-prepared work, that Atwood's Key, erroneously called Samana on many charts, is the original Guanahari of Columbus, renamed by him S. Salvador, also that Crooked Island and Acklin Island are the Maria de la Concepcion of Columbus and the true Samana of succeeding navigators in the sixteenth century. The last supposition is unquestionably correct. Crooked, Acklin, and Fortune Islands, which from the narrowness of the channels dividing them may have been, and very probably were, united four centuries ago, are plainly the Samana of the Dutch charts of the seventeenth century, and are so named on the excellent chart engraved in 1775 for Bryan Edwards's "History of the West Indies," but the view that Atwood's Key is identical with Guanahari is original, and is neither borne out by any old chart, nor by Columbus's description. This small island is conspicuously wanting in the one physical feature by which Guanahari is to be identified "*una laguna en medio muy grande.*" There is no lake or lagoon in it, nor does its distance from Samana tally at all with such slender particulars as have been left us by Columbus respecting his proceedings. The name S. Salvador has attached, not to Atwood's Key, but to Cat Island, one of the Bahamas; it is true that modern research has shifted it, but only to the next island, and on very good grounds. Cat Island is not *muy llana*, very level; on the contrary, it is the most hilly of all the Bahamas, and it has no lake or lagoon. Watling Island, a little to the south-east of Cat Island, and now generally recognised as the true Guanahari or S. Salvador, is very level; it has a large lagoon, it satisfies history as to the proceedings of Columbus for the two days following his discovery, by being very near the numerous islands of Exuma Sound, and I think few impartial persons can doubt the justice of the conclusion of the late Admiral Becher and of Mr. Major as to its identity; there are difficulties in the interpretation of Columbus's log on any hypothesis, but there is one little "undesigned coincidence" which to my mind goes far to carry conviction. Columbus, when he sighted land, was greatly in want of water, and he continued cruising about among the small islands in search of it for some days. Clearly, therefore, the *laguna* on Guanahari was not a fresh-water lake; nor is the lagoon on Watling Island fresh water, and so it exactly meets the case.

The report of Lieut. Raymond P. Rodgers, of the United States Navy, on the state of the Canal Works at Panama so lately as January 25 last, which has doubtless been eagerly read by many present, leaves me little to say on that great enterprise. Perhaps the following official returns of the amount of excavation effected in cubic metres (a cubic metre is 1·308 cubic yards) will enable the audience to realise its progress:—

	Total excavated	In each month
1883 October	2,042,034	
1883 November ...	2,375,534	333,300
1883 December ...	2,760,534	385,000
1884 January	3,340,534	580,000
1884 February	3,974,191	633,657
1884 March	4,590,022	615,831

The total quantity of excavation to be done in a length of 46·6 miles is estimated at 100,000,000 cubic metres, but the rapid augmentation of quantity shows that the limit has not been attained. This is no place to speak of the stimulus given by this great work to mechanical invention or the gigantic power of the machines employed, which will probably receive attention in another Section, but I may mention the two great problems which still await solution. The first is how to deal with the waters of the River Chagres; the second is how to manage a cutting nearly 400 feet deep (110 m. to 120 m.). The Chagres is a river as large as the Seine, but subject to great fluctuations of volume; it cuts the line of the canal nearly at right angles, and for obvious reasons it is impossible to let it flow into it. It is proposed to arrest the stream by an enormous dyke at Gamboa, near the divide. It will cross a valley between two hills, and be 1050 yards long at the bottom, 2110 yards at the top, 110 yards thick at the base, and 147 feet in greatest height. Out of the reservoir so constructed it is proposed to lead the overflow by two artificial channels, partly utilising the old bed. The cutting will be nearly 500 feet wide at the top (150 m.), with the sides at a slope of ½. It is proposed to attack it by gangs or parties working on twelve different levels at the same time, one each side of the summit, dividing the width at each level into five parallel sections. Thus there will be 120 gangs at work together, and it is confidently hoped that the whole will be really finished in 1888, the date long since assigned for its completion by M. de Lesseps. There is practically no other project now competing with it: for the proposed routes by the Isthmus of Tehuantepec, the Atrato, and San Blas, may be regarded as almost universally given up; both the latter would involve the construction of ship tunnels on a scale to daunt the boldest engineer. The so-called Caledonia route has not stood the test of examination. There remains but the Nicaragua route, and this, while practicable enough, has failed to attract capitalists, and is environed by political and other difficulties, which would leave it, if completed, under many disadvantages as compared with its rival. Among the latter must be named the necessity for rising by locks to the level of the Lake of Nicaragua (108 feet).

It is very tempting to speculate on the probable consequences of bringing the Hispano-Indian Republics bordering on the Pacific into such early contact with the energies of the Old World, but these speculations belong to politics rather than geography; moral transformations, we know, are not effected so easily as the conquest over physical difficulties.

Sir J. H. Lefroy then alluded at some length to recent progress in African exploration; then turning to Central Asia he went on:—

The Russian project for diverting the Oxus or Amu Darya from the Sea of Aral into the Caspian, remains under investigation. We learn from the lively account of Mr. George Kennan, a recent American traveller, that there is more than one motive for undertaking this great work, if it shall prove practicable. He states that the lowering of the level of the Caspian Sea, in consequence of the great evaporation from its surface, is occasioning the Russian Government great anxiety, that the level is steadily but slowly falling, notwithstanding the enormous quantity of water poured in by the Volga, the Ural, and other rivers. In fact, Col. Venukof says that the Caspian is drying up fast, and that the fresh-water seals, which form so curious a feature of its fauna, are fast diminishing in number. At first view there would not appear great difficulty in restoring water communication, the point where the river would be diverted being about 216 feet above the Caspian; but accurate levelling has shown considerable depressions in the intervening tract. As the question is one of great geographical interest we may devote a few minutes to it. It is not to be doubted that the Oxus, or a branch of it, once flowed into the Caspian Sea. Prof. R. Lenz, of the Russian Académie Impériale des Sciences, sums up his investigation of ancient authorities by affirming that there is no satisfactory evid[illegible] of its ever having done so before the year 1320;

passages which have been quoted from Arab writers of the ninth century only prove, in his opinion, that they did not discriminate between the Caspian Sea and the Sea of Aral. There is evidence that in the thirteenth and fourteenth centuries the river bifurcated, and one branch found its way to the Caspian, but probably ceased to do so in the sixteenth century. This agrees with Turcoman traditions. Even so late as 1869 the waters of the Oxus reached Lake Sara Kamysh, 80 or 90 miles from their channel, in a great flood, as happened also in 1850, but Sara Kamysh is now some 49 feet lower than the Caspian, and before they could proceed further an immense basin must be filled. The difficulties then of the restoration by artificial means of a communication which natural causes have cut off, are (*a*) the disappearance of the old bed, which cannot be traced at all over part of the way; (*b*) the possibility that further natural changes, such as have taken place on the Syr-Daria, may defeat the object; (*c*) the immense expenditure under any circumstances necessary, the distance being about 350 miles, which would be out of all proportion to any immediate commercial benefit to be expected. We may very safely conclude that the thing will not be done, nor is it at all probable that Russian finances will permit the alternative proposal of cutting a purely artificial canal by the shortest line, at an estimated expense of 15,000,000 to 20,000,000 roubles.

We have had, I think, no news of the intrepid Russian traveller, Col. Prjevalsky, who started from Kiakhta on November 20, of later date than January 20, when he had reached Alashan, north of the Great Wall. He had for the third time crossed the great Desert of Gobi, where he experienced a temperature below the freezing-point of mercury, and was to start for Lake Kuku-nor (+ 10,500 feet) the following day, thence to proceed to Tsaidam, where he proposed to form a depot of stores and provisions, and, leaving some of his party here, to endeavour to reach the sources of the Yang-tse-kiang, or Yellow River. It was his intention to devote the early part of the present summer to exploration of the Sefani country, situated between Kuku-nor to the north and Batan to the south—a country likely to yield an abundant harvest of novelty in natural history—afterwards to transfer his party to Hast, in Western Tsaidam, which may be reached next spring. From this point the expedition will endeavour first to explore Northern Thibet, which is his main object, in the direction of Lhasa and Lake Tengri-nor, and then returning northward, cross the Thibet plateau by new routes to Lake Lob-nor. After the re-assembly of the expedition at this point, it will probably regain Russian territory at Issyk-kul. Col. Prjevalsky is accompanied by two officers, an interpreter, and an escort of twenty Cossacks.

As you are aware, we have been chiefly indebted to natives of India for several years past for our knowledge of the regions beyond the British boundary. Mr. McNair, of the Indian Survey Department, who received the Murchison premium of this year, is the first European who has ever penetrated so far as Chitral, which is only 200 miles from Peshawur. In various disguises, however, natives, carefully instructed, have penetrated the neighbouring but unneighbourly regions of Afghanistan, Kashmir, Turkestan, Nepaul, Thibet—in almost every direction—and these achievements were crowned by one of them, known as A-k, reaching Saitu or Sachu, in Mongolia, in 1882, and thence returning in safety to India, after an absence of four years. His route took him to Darchendo or Tachialo (lat. 31°), the most westerly point reached by the late Capt. W. J. Gill, R.E., in 1877, and thus connects the explorations of that accomplished and lamented traveller with Central Asia. A-k has brought fresh evidence that the Sanpoo and the Brahmapootra are one; the quite modern opinion that the former flows into the Irrawaddy being shown to be groundless. After draining the northern slopes of the Himalayas, the Brahmapootra makes a loop round their eastern flanks where it has been called the Dehang, and thence, as everybody knows, flows westerly to join the Ganges; the maps have been shown in this instance to be right. The travels of these native explorers, their stratagems and their disguises, their hazards and sufferings, their frequent hair-breadth escapes, are teeming with excitement. One of them describes a portion of his track at the back of Mount Everest, as carried for a third of a mile along the face of a precipice at a height of 1500 feet above the Bhotia-kosi River, upon iron pegs let into the face of the rock, the path being formed by bars of iron and slabs of stone stretching from peg to peg, in no place more than 18 inches, and often not more than 9 inches, wide. Nevertheless this path is constantly used by men carrying burdens.

One of the finest feats of mountaineering on record was performed last year by Mr. W. W. Graham, who reached an elevation of 23,500 feet in the Himalayas, about 2900 feet above the summit of Chimborazo, whose ascent by Mr. Whymper in 1880 marked an epoch in these exploits. Mr. Graham was accompanied by an officer of the Swiss army, an experienced mountaineer, and by a professional Swiss guide. They ascended Kabru, a mountain visible from Darjeeling, lying to the west of Kanchinjunga, whose summit still defies the strength of man.

And here I may refer to that great work, the Trigonometrical Survey of India. The primary triangulation, commenced in the year 1800, is practically completed, although a little work remains to extend it to Ceylon on one side and to Siam on the other. Much secondary triangulation remains to be executed, but chiefly outside the limits of India proper. The Pisgah views, by which some of the loftiest mountains in the world have been fixed in position, sometimes from points in the nearest Himalayas, 120 miles distant, only serve to arouse a warmer desire for unrestrained access. The belief long entertained that a summit loftier than Mount Everest exists in Thibet is by no means extinct, but it is possible that the snowy peak intended may prove eventually to be the Mount Everest itself of the original Survey. Still, however, science, in spite of fanatical obstruction, makes sure advances. The extraordinary learning and research by which Sir H. Rawlinson was enabled a few years since to expose a series of mystifications or falsifications relating to the Upper Oxus, which had been received on high geographical authority, can never be forgotten. That river has now been traced from its sources in the Panjab, chiefly by native explorers, and to them we may be said to be indebted for all we know of Nepaul, from which Europeans are as jealously excluded as they are from the wildest Central Asian Khanate, although Nepaul is not so far from Calcutta as Kingston is from Quebec.

Carrying their instruments to the most remote and inaccessible places, and among the most primitive hill tribes, the narrative reports of the officers of the Indian Survey are full of ethnographic and other curious information. Take for example the account given by Mr. G. A. McGill, in 1882, of the Bishnoies of Rajpútana, a class of people, he says, who live by themselves, and are seldom to be found in the same village with the other castes. "These people hold sacred everything animate and inanimate, carrying this belief so far that they never even cut down a green tree; they also do all in their power to prevent others from doing the same, and this is why they live apart from other people, so as not to witness the taking of life. The Bishnoies, unlike the rest of the inhabitants, strictly avoid drink, smoking, and eating opium; this being prohibited to them by their religion. They are also stringently enjoined to monogamy and to the performance of regular ablutions daily. Under all these circumstances, and as may be expected, the Bishnoies are a well-to-do community, but are abhorred by the other people, especially as by their domestic and frugal habits they soon get rich, and are the owners of the best lands in the country."

In one particular the experience of the Indian Survey carries a lesson to this country. "A constantly growing demand," says Gen. Walker, "has risen of late years for new surveys on a large scale, in supersession of the small-scale surveys which were executed a generation or more ago. . . . The so-called topographical surveys of those days were in reality geographical reconnaissances sufficient for all the requirements of the Indian atlas, and for general reproduction on small scales, but not for purposes which demand accurate delineation of minute detail." We have in the Canadian North-West a region which has not yet passed beyond the preliminary stage, and it would probably be possible to save much future expenditure by timely adoption of the more rigorous system. There is perhaps no region on the globe which offers conditions more favourable for geodesy than the long stretch of the western plains, or where the highest problems are more likely to present themselves in relation to the form and density of the earth. The American surveyors have already measured a trigonometrical base of about 10·86 miles in the Sacramento Valley, the longest I believe as yet measured in any country (the Yolo Base) and reported to be one of the most accurate.

The President then referred to Australian exploration, the International Polar Expeditions, deep-sea research, and railway extension, and concluded as follows:—

I have now touched lightly upon all the points which appear to me to be most noticeable in the recent progress of geographical science; but before I resume my seat I cannot deny myself the pleasure of alluding to that important measure of social reform, so simple in its application, so scientific in its basis, for which you are indebted to the perseverance and enthusiasm of my friend Mr. Sandford Fleming, C.E. I mean, of course, the agreement to refer local time on this continent to a succession of first meridians, one hour apart. There are many red-letter days in the almanac of less importance than that memorable November 18, 1883, which saw this system adopted, whether we consider its educational tendency or its influence on the future intercourse of unborn millions. It is a somewhat memorable evidence also that agreement upon questions of general concern is not that unattainable thing which we are apt to consider it. The next step will not be long delayed; that is the agreement of the civilised world to use one first meridian—Paris, Ferrol, Washington, Rio de Janeiro, gracefully, as I venture to hope, giving that precedency to Greenwich which is demanded by the fact that an overwhelming proportion of the existing nautical charts of all nations, and of maps and atlases in most of them, already refer their longitudes to that meridian; no other change would be so easy or so little felt.

SECTION G

MECHANICAL SCIENCE

OPENING ADDRESS BY SIR F. J. BRAMWELL, F.R.S., V.P.INST.C.E., PRESIDENT OF THE SECTION

IN a family of seven children there are two who are of paramount importance: the eldest, at the one end of the scale, important because he is the heir, the first-born; and at the other end of the scale, the little Benjamin, important because he is the last, the youngest, and the dearest. The position of little Benjamin is not, perhaps, quite as honourable as that of the heir, and not, when the family breaks up, by any means as good; but while the family holds together, Benjamin receives an amount of attention and consideration that does not fall to the lot of any one of the intermediates, not even to the heir himself. But there is one risk about Benjamin's position, a risk that cannot appertain to the post of the first-born; little Benjamin may be deposed by the advent of a lesser Benjamin than himself, whereas the first-born becomes (if possible) still more the first-born for each addition to the family. Perhaps some of you may say, Be it so; but what has this to do with the address of the President of Section G? Those who make this inquiry, however, certainly have not present to their minds the change that has this year taken place. Up to and including the Southport meeting, Section G was the little Benjamin among the seven sons of the B.A. (I will not waste your time by giving the name of the Association in full, nor will I affront you by using an abbreviation which is occasionally improperly applied), but at Montreal appears Section H, and G becomes relegated among those uninteresting members of the family who are neither the important head nor the cherished tail. I grieve for Benjamin, and I think the present occasion an apt one for magnifying Section G. Apt for two reasons: the foregoing one, that H has deposed it from its position; the other, that we are meeting in Montreal—and in reference to this latter reason let me ask, Is it not the fact that to the labours of the men who have been, or are (or ought to be) members of Section G is due the possibility of the meeting taking place on this side of the Atlantic?

At our jubilee meeting at York, I called the attention of the Section to the fact that in 1831, when the Association first met in that city, they arrived there laboriously by the stage-coach, and that practically the Manchester and Liverpool, the Stockton and Darlington, and some few others, were the only railways then in existence. I also called their attention to the fact that in 1831 there were but very few steamers. I find the total number registered in the United Kingdom in that year was only 447. If under this condition of things the proposition had been made in 1832 at Oxford, as it was made in 1882 at Southampton, that the next meeting but one of the Association should take place in Montreal, the extreme probability is that the proposer would have been safely lodged in a lunatic asylum for suggesting that that which might have involved a six-weeks' voyage out, and a four-weeks' voyage back, could ever be seriously entertained. Further, to give once more the hackneyed quotation, some few years after this, *i.e.* in 1836, Dr. Lardner established, to his own satisfaction conclusively, that no vessel could ever steam across the Atlantic the whole way—a striking instance of the mistakes made by scientific speculation—a branch of science widely differing in the value of its results from those branches which deal with absolute demonstration. Undeterred, however, by such adverse opinion, the engineers "kept on pegging away," experimenting, improving, and progressing, until the scientific speculation was met with the hard fact of the Atlantic voyage steamed the whole way by the *Sirius* and by the *Great Western* in 1838. The impossible was proved to be the possible, and from that day to this the advancement of steam ocean navigation has continued. The six-weeks' voyage, sailing westward, of the year 1831, has become converted into but little over six days. And thus it is that that which would have been a mad proposition in the year 1832 became a perfectly rational one in 1882; and the deliberations of the General Committee on the proposition were not directed as to whether it would be possible to convey the members with certainty, expedition, and economy across the Atlantic, but as to whether it was expedient or not on general grounds to hold for the first time a meeting of the British Association elsewhere than in some city of the United Kingdom. I say again that the possibility of such a meeting is absolutely due to the engineer, and that therefore, on this ground, the present is an appropriate occasion to magnify G, the Mechanical Section of this Association.

It is true that the man who looks only at that which is on the surface may say, "You arrogate too much to yourselves. You ignore (to which I say, Heaven forbid!) the skill and daring of your sailors. You ignore commercial enterprise. You ignore the development of iron and steel manufacture, which have enabled you to build the steamers of the present day. You ignore the increased output of the best steam coal in the world, and you attribute the whole result to the engineer." Such an objector would be in the condition of that man who, in answer to George Stephenson's question, "What is causing that railway train to move?" said, "Why, I suppose the coal that is burning in the locomotive;" and who was met by that grand and comprehensive answer, that it was the "Sun," for the coals were a consequence, and not a first cause. Similarly I venture to say that the mechanical engineer may lay claim to be the central source which has vivified and given rise to the improvements in the manufacture of iron and steel, in the construction of engines, and in the development of our collieries.

There are those I know who object that Section G deals too little with pure science, too much with its applications. It may be, as the members of Section G might retort, that it is possible to attend so much to pure science as to get into the unchecked region of scientific speculation, and that, had the members of Section G been debarred from the application of science, the speculation of Dr. Lardner might to the present day have been accepted as fact.

I have quoted it before, but it has so important a bearing on this point, and comes from a man of such high authority, that I cannot refrain from once more giving you Dr. Tyndall's views on this question:—

"The knowledge of Nature and the progressive mastery over the powers of Nature imply the interaction of two things—namely, thought conceived and thought executed; the conceptions of the brain, and the realisation of those conceptions by the hand. The history of the human intellect hardly furnishes a more striking illustration of this interaction of thought and fact than that furnished by the Association of Physics and Engineering. Take for instance the case of steam. Without knowing its properties, the thought of applying steam could not have arisen, hence the first step was physical examination. But that examination suggested practice, and the steam-engine at last saw the light; thus experimental physics was the seedling from which the steam-engine sprang. But the matter did not end here; the positions of debtor and creditor were soon reversed, for the stupendous operations of the steam-engine forced men of thoughtful philosophic minds to inquire into the origin of the power of steam. Guess succeeded guess, inspiration succeeded inspiration; the ever-present fact of our railways, and our power-looms, and our steamships gave the mind no rest until it had answered the question, How are heat and steam, its instruments, related to mechanical power? Had the works of the engineer not preceded the work of the natural philosopher, this question would never have been asked with the emphasis, nor pursued with the vigour, nor answered with the success, which have attended it. It was the intellectual activity excited by the work which the civil engineers of England had accom-

plished that gave to philosophy the theory of the conservation of energy, including the dynamical theory of heat. . . . The engineering genius of the future is certain to derive from this theory strength and guidance. Thus necessarily has thought originated fact, and fact originated thought. In the development of science these two powers are coequal; each in turn ceasing to be a consequence, and becoming a creative cause. The Atlantic cable also had its small beginnings in the laboratory of the physical inquirer. Here, as before, experimental physics led the way to engineering facts of astounding magnitude and skill. But here also the positions of debtor and creditor have been reversed, for the work of the engineer has caused the physical inquirer to pursue his investigations with a thoroughness and vigour, and has given to those investigations a scope and magnitude, which, without the practical stimulus, would have been impossible. The consequence is that the practical realisation of sending electric messages along the bottom of the Atlantic has been an immense augmentation of our knowledge regarding electricity itself. Thus does the human intelligence oscillate between sound theory and sound practice, gaining by every contact with each an accession of strength. These two things are the soul and body of science. Sever sound theory from sound practice, and both die of atrophy. The one becomes a ghost and the other becomes a corpse."

I think all men, even although they be followers of science in its purest and most abstract form, must agree that these words are words of sound sense, well worthy of being borne in mind and of being acted on, and will, therefore, concur in the propriety of Section G dealing with engineering subjects generally as well as with abstract mechanical science. Once admitting this, I may ask—certain what the answer must be—whether there is any body of men who more appreciate and make greater use of the applications of pure science than do the members of this Section. Surely every one must agree that we engineers are those who make the greatest practical use not only of the science of mechanics but of the researches and discoveries of the members of the other Sections of this Association.

Section A, *Mathematical and Physical Science*. The connection between this Section and Section G is most intimate. With any ordinary man I should have referred, in proof of this intimate connection, to the fact that the President of A this year is a member of the Council of the Institution of Civil Engineers, but when I remind you that it is Sir William Thomson who fills this double office, you will see that no deduction such as I have hinted at can be drawn from his dual functions, because the remarkable extent and versatility of his attainments qualify him for so many offices, that the mere fact of his holding some one double position is no certain evidence of the intimate connection between the two. But setting aside this fact of the occupancy of the chair of A by a civil engineer, let us remember that the accomplished engineer of the present day must be one well grounded in thermal science, in electrical science, and for some branches of the profession in the sciences relating to the production of light, in optical science, and in acoustics; while, in other branches, meteorological science, photometrical science, and tidal laws are all-important. Without a knowledge of thermal laws, the engineer engaged in the construction of heat-motors, whether they be the steam-engine, the gas-engine, or the hot-air engine, or engines depending upon the expansion and contraction under changes of temperature of fluids or of solids, will find himself groping in the dark; he will not even understand the value of his own experiments, and therefore will be unable to deduce laws from them; and if he makes any progress at all, it will not guide him with certainty to further development, and it may be that he will waste time and money in the endeavour to obtain results which a knowledge of thermal science would have shown him were impossible. Furnished, however, with this knowledge, the engineer, starting with the mechanical equivalent of heat, knowing the utmost that is to be attained, and starting with the knowledge of the calorific effect of different fuels, is enabled to compare the results that he obtains with the maximum, and to ascertain how far the one falls short of the other; he sees even at the present day that the difference is deplorably large, but he further sees in the case of the steam-engine, that which the pure scientist would not so readily appreciate, and that is, how a great part of this loss is due to the inability of materials to resist temperature and pressure beyond certain comparatively low limits; and he thus perceives that unless some hitherto wholly unsuspected, and apparently impossible, improvement in these respects should be made, practically speaking the maximum of useful effect must be far below that which pure science would say was possible. Nevertheless, he knows that within the practical limits great improvements can be made; he can draw up a debtor and creditor account, as Dr. Russell and myself have done, and as has been done by Mr. William Anderson, the engineer, in the admirable lecture he gave at the Institution of Civil Engineers in December last, on "The Generation of Steam and the Thermodynamic Principles involved." Furnished with such an account the engineer is able to say, in the language of commerce, I am debtor to the fuel for so many heat-units, how, on the credit side of my account, do I discharge that debt? Usefully I have done so much work, converted that much heat into energy. Uselessly I have raised the air needed for combustion from the temperature of the atmosphere to that of the gases escaping by the chimney; and he sets himself to consider whether some portion of the heat cannot be abstracted from these gases and be transmitted to the in-coming air. As was first pointed out by Mr. Anderson, he will have to say a portion of the heat has been converted into energy in displacing the atmosphere, and that, so far as the gaseous products of the coal are concerned, must, I fear, be put up with. He will say, I have allowed more air than was needed for combustion to pass through the fuel, and I did it to prevent another source of loss—the waste which occurs when the combustion is imperfect; and he will begin to direct his attention to the use of gaseous or of liquid fuel, or of solid fuel reduced to fine dust, as by Crampton's process, as in these conditions the supply may be made continuous and uniform, and the introduction of air may be easily regulated with the greatest nicety. He will say, I am obliged to put among my credits—loss of heat by convection and radiation, loss by carrying particles of water over with the steam, loss by condensation within the cylinder, loss by strangulation in valves and passages, loss by excessive friction or by leakage; and he will as steadily apply himself to the extinction or the diminution of all such causes of loss as a prudent Chancellor of the Exchequer would watch and cut down every unproductive and unnecessary expenditure. It is due to the guidance of such considerations as these that the scientific engineer has been enabled to bring down the consumption of fuel in the steam-engine, even in marine engines such as those which propelled the ship that brought us here, to less than one-half of that which it was but a few years back. It is true that the daily consumption may not have been reduced, that it may be even greater, but if so it arises from this, that the travelling public will have high speed, and at present the engineer, in his capacity of naval architect, has not seen how—notwithstanding the great improvements that have been made in the forms of vessels—to obtain high speed without a large expenditure of power. I anticipate, from the application of thermal science to practical engineering, that great results are before us in those heat-motors, such as the gas-engine, where the heat is developed in the engine itself. Passing away from heat-motors, and considering heat as applied to metallurgy, from the time of the hot blast to the regenerative furnace, it is due to the application of science by the engineer that the economy of the hot blast was originated, and that it has been developed by the labours of Lowthian Bell, Cowper, and Cochrane. Equally due to this application are the results obtained in the regenerative furnace, in the dust furnace of Crampton, and in the employment of liquid fuel, and also in operations connected with the rarer metals, the oxygen furnace, and the atmospheric gas furnace, and, in its incipient stage, the electrical furnace. To a right knowledge of the laws of heat and to their application by the engineer, must be attributed the success that has attended the air-refrigerating machines, by the aid of which fresh meat is, at the end of a long voyage, delivered in a perfect condition; and to this application we owe the economic distillation of sea-water by repeated ebullitions and condensations at successively decreasing temperatures, thus converting the brine that caused the Ancient Mariner to exclaim, "Water, water everywhere, nor any drop to drink," into the purest of potable waters, and thereby rendering the sailor independent of fresh-water storage.

With respect to the application by the engineer of electrical science, it is within the present generation that electricity has passed from the state of a somewhat neglected scientific abstraction into practical use: first, by the establishment of the land telegraph, then by the development into the submarine cable, by means of which any one of us visitors here in Canada may be in instant communication with his own country, and may be so without a selfish exclusive occupation of the cable, for once more the application of science has solved that apparently impossible

problem of employing a single wire to be at one and the same time the transmitter of multiple electric messages, and messages in opposite directions. Then, thanks to the application of Faraday's great discovery of induced electricity, there has been, during the last quarter of a century, the progressive development of the dynamo machine, whereby the energy of ordinary motors, such as steam-engines, is converted into electrical energy, competent to deposit metals, to (as has already been said) fuse them, to light not only isolated buildings but extensive areas of towns and cities, and to transmit power to a distance, whether for manufacturing purposes or for the railway or tramcar; and thus the miracle is performed of converting a waterfall into a source of light, as at Sir William Armstrong's house, or into the origin of power for a railway, as at the Giant's Causeway. To the application of electrical science is due the self-exciting of the dynamos and the construction of secondary batteries, enabling a development of electricity to be continued for many hours. In the United Kingdom general electric lighting, that is to say, the lighting of large sections of a town from a central station, has been stopped by the most unwise, because most unjust, conditions imposed by the Government General Electric Lighting Act of 1882. A new and meritorious industry, which should have been granted the same privileges as are accorded to other industrial undertakings needing Parliamentary powers, was subjected to this most unjust condition: that at the end of twenty-one years the public authority of the town or place lighted should have the option of buying the undertaking for the then value of the mere materials, and that, if the authority did not choose to purchase (for it was not bound to buy), at every subsequent five-year period this option should re-arise; that is to say, that a new undertaking, which would require years for its general acceptance (for the public is slow to take up a novelty), was, after the experimental and non-paying stage had been passed, to be practically forthwith taken away for a mere fraction of the capital that had been outlaid if the undertaking paid, but was not to be taken away if it did not pay. Such, in spite of the teaching of Section F, is the condition to which our Government has arrived in respect of economic science. The next electrical matter I have to touch upon, that of the telephone and microphone, with which will for ever be associated the names of Graham-Bell, Edison, and Hughes, has, as regards the public use of the telephone, been all but similarly treated in the United Kingdom. It has been declared to be within the telegraphic monopoly given by Parliament to the Post Office nine years before the telephone was invented, and the power to use it depends entirely upon the grace and favour of the Post Office, a grace and favour not always accorded; and even when accorded, coupled with limitations as to distance, and coupled with a condition of payment of 10 per cent. of the gross receipts by the companies to the Post Office as a royalty; and all this because Government has become a trader in electrical intelligence, and fears the competition of the telephone with its telegraphs.

No one in the ship-loving countries of England, Canada, and the United States can refrain from feeling the warmest interest in all connected with navigation, and we know how frequently, alas! the prosperous voyage across the wide and fathomless ocean ends in shipwreck and disaster when the wished-for shore is approached, and when the sea is comparatively shallow. Except for the chance of collision, there is in a staunch ship little danger in the open ocean, but on nearing the shore, not only is the liability to collision increased, but shoals and sunken rocks render navigation perilous, and it is on the excellence of the lighthouses and lightships that (coupled with soundings) the sailor relies. These structures and appliances are confided to the engineer, and to be efficient they require him to be able to apply the teachings of Section A in optical science, and in the case of fogs, or as regards buoys at night-time, the science of sound. I parenthetically alluded to soundings as one (indeed a principal one) of the safeguards of ships when approaching shore. It is important in these days of high speed that these should be made with ease and without the necessity of stopping the ship, or even of diminishing its velocity. Sir William Thomson, by the application of the science of pneumatics, has enabled this to be done. Again, most important is it that the compass, amidst all the difficulties attendant upon its being situated on an iron or steel structure, should be trustworthy. And here Sir William has applied the science of magnetism in his improved compass to the practical purposes of navigation.

To go to another important branch of engineering—water-supply. The engineer dealing with a district to be fed from the surface will find himself very deficient if he have not the power of applying the science of meteorology to the work that he has in hand; he must know, not the average rainfall, for that is of but little use to him, but the maximum, and, most important of all, the minimum, rainfall over a consecutive period of years: the maximum, so that he may provide sufficient channels and by-washes for floods; the minimum, so as to provide sufficient storage. He must know what are the losses by evaporation, what are the chances of frost interfering with his filters and with his distributive plant.

Coming to the mathematical side of Section A—whether we consider the naval architect preparing his design of a vessel to cleave the waves with the least resistance at the highest speed, or whether we consider the unparalleled series of experiments of that most able Associate of Naval Architects, the late William Froude, carried out as they were by means of models which were admirable in their material, their mode of manufacture with absolute accuracy to the desired shape, and their mode of traction and of record, we must see that both architect and experimenter should be able to apply mathematical science to their work, and that it is in the highest degree desirable that they sh uld possess, as Froude did, those most excellent gifts, science and practical knowledge.

Again, the mathematical side of Section A has to be applied by engineers when considering the strength and proportion of boilers, ships, bridges, girders, viaducts, retaining walls, and in short the whole of the work with which an engineer is intrusted. Notable instances of great bridges will occur to all our minds, especially meeting as we are in this continent of grand streams, Eads' St. Louis Bridge, Roebling's Niagara Bridge, and his and and his sons' East River Bridge, Gzowski's International Bridge, and, going back to our own land, Fowler and Baker's Bridge over the Forth.

Passing from Section A to Section B, there is evidently so much overlapping of these Sections that a good deal that I have said in reference to Section A might properly have been reserved for Section B. The preparation from the ore of the various metals is in truth a branch of engineering; but to enable this to be accomplished with certainty, with economy, involving the not throwing away of that which is called the waste product but which is frequently a valuable material, it is essential that the engineer and the chemist should either be combined in one and the same person, or should go hand in hand. In the manufacture of pig iron it is absolutely necessary that the chemical constituents of the ore, the fuel, and the flux should be thoroughly understood, and that the excellence of the process followed should be tested by an analysis of the slag. For want of this chemical knowledge, thousands upon thousands of tons of bad pig iron have been made, and thousands upon thousands of tons were formerly left in the issuing slag. Similar remarks apply to the production of lead and of copper from the ores, and still more do they apply to that great metallurgical manufacture of the last few years—"steel." In the outset steel was distrusted, because of the uncertainty of its behaviour, but the application of chemical science now enables the manufacturer to produce with precision the material required to fulfil the physical tests imposed by the engineer.

Reverting to the water engineer, the chemist and the microscopist have their sciences applied to ascertain the purity of the intended source, and, as in the case of Clarke's beautiful process, by the application of chemistry, water owing its hardness to that common cause, carbonate of lime, is rendered as soft as the water from the mountain lake. Taking that other branch of engineering commonly coupled with water, viz. the supply of gas, the engineer is helpless without the application of chemistry. From the examination of the coal to be used to the testing of the gas to be supplied, there is not one stage where chemical science is not necessary. The consumer requires gas which shall be as nearly as possible a pure hydrocarbon of high illuminating power, and it might well have been that a person to whom was delivered the crude gas as it issued from the retort would have said, "Certain things may be separated out more or less, but to practise on a wholesale scale the delicate operations which will be needed to cleanse the illuminating gas from its multifarious accompanying impurities is a hopeless undertaking, and must be so, if for no other reason than this—the excessive cost that would be entailed." But what are the facts? Although I for one do not like to sit in a room where gas is burnt, unless special provision is made for taking away the products of combustion, the engineer of the present day, thanks to the application of chemical science, delivers gas to the consumer in a state of comparative purity (although it may have been made from impure

coal) which but a few years ago would have been deemed impossible; and so far is this improvement from being attended with extra cost, that the residual products not now uncommonly all but pay the whole cost of the coal, and in some rare instances even leave a slight profit to go towards the charge of labour. Again, it is by the application of chemical science in the dynamite and the gun-cotton of the present day that the engineer is enabled to prepare submarine foundations, to blast away shoals, and to drive tunnels through rock of a character that cannot be dealt with by mere cutting machines. Equally to the application of chemistry is it due that there are hopes, by the employment of lime cartridges, of breaking down coal without that risk of igniting fire-damp which is attendant upon the use of gunpowder. I need hardly observe that much more might most pertinently be said on the way in which the engineer applies chemical science. In fact, those ways are so multifarious that a volume might be written upon them, but I must pass on and ask you to consider how the engineer applies geological science, the science treated by Section C.

I have already spoken of the engineer supplying towns by water collected from the surface; even he, however, must have a knowledge of geology, for without it he will not know what places are apt for the huge reservoirs he constructs, nor where he can in safety make his enormous embankments. In this continent of vast lakes one feels it must excite a sensation of the ridiculous when a "Welsh lake" is spoken of, but I must ask you to believe you are in Liliput, and to imagine that the "Bala Pond" of 1100 acres in extent, is really "Bala Lake," as it is called. Within a few miles of that, our friends at the other end of the Atlantic steam ferry, the inhabitants of Liverpool, are now constructing under the engineering and advice of Mr. Hawksley, a waterworks which will involve the formation, I believe one may say the re-formation, of a lake, practically the same area as that of Bala, of some 80 feet in depth, and containing between the overflow and the point of lowest discharge nearly twelve thousand million gallons. This lake will be made by the throwing from side to side of the valley of a solid stone bank, 100 feet above the ground, 140 feet above the deepest part of the foundations, and 113 feet thick at its thickest part. Contrasted with Lake Superior this new lake will be small, a thing demanding a microscope even, but the bursting of the wall would liberate a body of water sufficient to carry death and ruin throughout a considerable district. It is, therefore, in the highest degree important that whether he be constructing the solid stone wall, or the more common earthen embankment with a puddle trench, the engineer should so apply geological science as to insure the safety of his work. But in those cases where the waterworks engineer has to derive the supply from underground sources, the application of this science is still more necessary; he must know whether he is likely to find a water-bearing stratification at all —if so, where it receives the rain from heaven, and the extent of the area which receives it; in what direction the water travels through it, what is the varying height of water in the different parts of the stratification giving the "head" to produce that travel; how far this height is likely to be affected by the pumping of the desired quantity; whether, if near the outflow into the sea, the pumping is likely to reverse the direction of the current, and to bring back brackish water, and whether the rocks are of such a character as to be liable to yield a water impregnated with iron or with lime, and whether these water-bearing rocks are accessible from the surface without the execution of costly and laborious work in passing through overlying stratifications of an unfit or it may be even of a dangerous character. It need hardly be said that the engineer when engaged in metalliferous mining, or in the extraction of coal or of petroleum, unless he applies the science of Section C, is but a haphazard explorer whose work is more likely to end in disaster than in success. Again, the engineer, when laying out a railway, has to consider the geological features of the country in determining the angles of his cuttings, and to determine where it becomes more economical to tunnel than to cut. Indeed, without the application of that science to engineering there are some enterprises on the feasibility of which the engineer would not be able to pronounce an opinion—a notable instance, the Channel Tunnel. The engineers, of whom I am one, said there is a material, the compact non-water-bearing grey chalk, which we have at a convenient depth on the English side and, is of all materials the most suitable; if that exist the whole way across, success is certain. Then came geological science, and that told the engineer that in France the same material existed; that it existed in the same position in relation to other stratifications as it existed in England; that the line of outcrop of the gault lying below it had been checked across; and that taken together these indications enabled a confident opinion to be expressed that it was all but certain this grey chalk stratification did prevail from side to side. The engineers believed it, an intelligent section of the public believed it, and came forward with their money; large sums were expended in England and in France on the faith of the repeated declaration of the English Government (of both sides of politics), that so long as the nation was not called on to contribute towards the cost of the work, it would hail with satisfaction the improved means of communication between England and the Continent; the experimental works were carried on from both sides with the happiest results, and then, when success appeared certain, the whole work was stopped by the incredible suggestion that in the event of a war the soldiers of England, and the science of England, could not defend a couple of rat-holes, holes 14 feet in diameter and 20 miles long, situated far below the surface of the sea, having a rapid dip from the shore to a low point, gradually rising from there to the centre of the length of the tunnel, so that the English end could be flooded with sea-water in twenty-five minutes up to the soffit of the arch at the dip; and in consequence of this incredible and much-to-be-ashamed-of scare it is due that one of the finest instances of civil engineering work in connection with the science of geology, and as I believe one of the most useful works that has ever been proposed, has been put a stop to.

To come to Section D, the botanical side of it is interesting to the engineer as instructing him in the locality and quality of the various woods that he occasionally uses in his work. With regard to that most important part of the work of D, which relates to "germs" and their influence upon health, the engineer deals with it thus far: he bears in mind that the water-supply must be pure, and that the building must be ventilated, and that excreta must be removed without causing contamination; thus the waterworks engineer, the warming and ventilating engineer, and the sewage engineer can (and do) all of them profit by the labours of Section D, and can by their works assist in giving practical value to the pure science of that section.

Section E, *Geography*. Probably in these days, when our kingdom at home and the old countries near us are all but full of the works of the engineer, there are few who take a greater interest in geography than he does, and I am quite sure there are none who make a more useful application of geographical knowledge for the benefit of mankind at large than does the engineer. Almost at the outset of this address I claimed to magnify Section G, on the ground that without the aid of its members we should not have had that practical lesson in geography which we have received by our visit here, a lesson that no doubt will be continued and amplified by many of us before we return to our homes. Whether it be by the ocean steamer or by the railway train, the enterprising geographical explorer is carried to or through countries which now, thanks to the engineer, are well known and settled, up to the beginning of the unknown and not settled; and thus his labours are lightened, he consumes his energies only upon his true work, brings back his report, which is, as I have said, studied by the engineer with a view to still further development, and thus, turn by turn, the geographer and the engineer carry civilisation over the face of the world.

Now to come to Section F, which treats of Economic Science. The matters with which this Section deals—birth-rate, death-rate, the increase or the diminution of populations, the development of particular industries in different localities, the varying rates of wages, the extent and nature of taxation, the cost of production, the cost of transport, the statistics of railway and of marine disasters, the consumption of fuel, and many matters which come within the purview of F, are of impo tance to the engineer. Guided by the information given him by the labours of this Section, he comes to the conclusion that a work having a particular object in view should or should not be undertaken. With the information derived from the past he judges of the future; he sees what provision should be made for prospective increase of population or of industries; he sees the chances of the commercial success of an undertaking or of its failure, and he advises accordingly.

I do not propose to say anything about Section H, for I have dealt with it as being still included within D.

I trust I have now established the proposition with which I set out, viz. that not only is Section G the Section of Mechanical Science, but it is emphatically the Section of all others that applies in engineering to the uses of man the several sciences

appertaining to the other Sections: an application most important in the progress of the world, and an application not to be lightly regarded, even by the strictest votaries of pure science, for it would be vain to hope that pure science would continue to be pursued if from time to time its discoveries were not brought into practical use.

Under ordinary circumstances I should have closed my address at this point, but there is a subject which at this, the first meeting of Section G after the meeting at Southport, must be touched upon. It is one of so sad a character that I have avoided all allusion to it until this the very last moment, but now I am compelled to grapple with it.

In the course of this address I have had occasion to mention several names of eminent men, many of them happily still with us, some of them passed away; but I doubt not you have been struck by the absence of one name, which of all others demands mention when considering physical science, and still more does it come vividly before us when considering the application of science to industrial purposes. I am sure I need not tell you that this name, which I can hardly trust myself to speak, is that of our dear friend William Siemens, whose contributions to science, and whose ability in the application of science, have for years enriched the transactions of this Section, and of Sections A and B, for in him were combined the mechanic, the physicist, and the chemist.

But a brief year has elapsed since he quitted the Presidential chair of the Association, and, with us at Southport, was taking his accustomed part in the work of this and of other Sections, apparently in good health, and with a reasonable prospect of being further useful to science for many valuable years to come. But it was not to be; he is lost to us, and in losing him we are deprived of a man whose electrical work has been second to none, whose thermic work has been second to none, and whose enlarged views justified him in embarking in scientific speculations of the grandest and most profound character. Whether or not his theory of the conservation of the energy of the sun shall prove to be correct, it cannot be denied that it was a bold and original conception, and one thoroughly well reasoned out from first to last.

I feel that, were I to attempt anything like the barest summary of his discoveries and inventions, I should set myself a task which could not have been fulfilled had I devoted the whole of the time I had at my command to the purpose. I had indeed thought of making his work the subject of my address, but I felt that his loss was so recent that I could not trust myself to attempt it. There is no need for me to dwell further upon this most painful topic. He was known to you all, he was honoured and loved by you all, and by every member of this Association he had so faithfully served, and over which he had so ably presided; and he enjoyed the respect and esteem of the best intelligence of England, the land of his adoption; of the Continent, his birthplace; and of Canada, and of the United States, whose populations are always ready to appreciate scientific talent and the resulting industrial progress. It is not too much to say that few more gifted men have ever lived, and that with all his ability and talent he combined a simplicity, a modesty, and an affectionate disposition that endeared him to all.

I am sorry to conclude my address to you in this mournful strain. I have endeavoured to confine my allusions to our dear friend within the narrowest limits, but if I have overstepped these I trust you will forgive me, remembering that "out of the fulness of the heart the mouth speaketh."

NOTES

We announce with great regret the death, yesterday, at the age of eighty-three years, of Mr. George Bentham, F.R.S., F.L.S., the eminent botanist.

The Committee which has been formed for the erection of a statue to the late Jean Baptiste Dumas at his native town, Alais (Gard), is an extensive one. The president is M. Pasteur, and the vice-presidents MM. J. Bertrand, F. de Lesseps, and Cauvet. The members of the Committee include all the names of scientific note in France. Among the foreign members are well-known men of all nationalities; the English members being Sir William Thomson, Dr. W. De La Rue, Prof. Williamson, and Dr. Frankland. There is besides a local Committee at Alais. With such powerful and wide support the monument is sure to be worthy of Dumas' reputation. Subscriptions should be sent to M. E. Maindrin, Palais de l'Institut de France, Paris.

The National Electrical Conference, convened by the U.S. Congress in connection with the Electrical Exhibition, began its sessions in Philadelphia on Monday. Addresses were made by the President of the Conference, Prof. Rowland of the Johns Hopkins University, Baltimore; also by Sir William Thomson, the Vice-President. The practical work of the Conference began on Tuesday afternoon with a discussion on the work of the United States Signal Office in relation to electrical observation. The Conference will hereafter discuss the necessity for a national bureau of electrical standards, the adoption of an international system of electrical units, and the theory of dynamo-electric machines. Prof. George Forbes of London delivered a lecture on dynamo-electric machinery on Tuesday evening.

The Iron and Steel Institute holds its annual meeting this year at Chester on September 23 and three following days. Among the papers and subjects for discussion are the following:—On the geology of Cheshire, by Mr. Aubrey Strahan, of H.M. Geological Survey, London; on improvements in the Siemens regenerative gas furnace, by Mr. Frederick Siemens, C.E., London; on recent improvements in the method of the manufacture of open-hearth steel, by Mr. James Riley, Glasgow, Member of Council; on a new form of regenerative furnace, by Mr. F. W. Dick, Glasgow; on the manufacture of crucible steel, by Mr. Henry Seebohm, Sheffield; on the recovery of by-products from coal, more especially in connection with the coking and iron industries, by Mr. Watson Smith, Owens College, Manchester; on the most recent results obtained in Germany in utilising the by-products from Otto and other coke ovens, by Dr. C. Otto, Dalhausen; on the North-Eastern Steel Company's Works at Middlesbrough, and their products, by Mr. Arthur Cooper, Middlesbrough; on the spectroscopic examination of the vapours evolved on heating iron, &c., at atmospheric pressure, by Mr. John Parry, Ebbw Vale.

The museum recently opened at Newcastle-on-Tyne by the Prince of Wales is a very fine building indeed, and of course is quite unconnected with the public library. The building contains the collections of the well-known Natural History Society of Northumberland, Durham, and Newcastle-on-Tyne, and will cost 42,000*l*. Of this 38,000*l*. have been raised by public subscription.

The preliminary programme of the Central Institution for Technical Education has been issued. The object of the Central Institution, it states, is to give to London a College for the higher technical education, in which advanced instruction shall be provided in those kinds of knowledge which bear upon the different branches of industry, whether manufactures or arts. The Institution is intended to afford practical scientific and artistic instruction which shall qualify persons to become (1) technical teachers; (2) mechanical, civil, electrical, chemical, and sanitary engineers, architects, builders, and decorative artists; (3) principals, superintendents, and managers of manufacturing works. The main purpose of the instruction to be given in this Institution will be to point out the application of different branches of science to various manufacturing industries; and in this respect the teaching will differ from that given in the Universities and in other institutions in which science is taught rather for its own sake than with the view to its industrial application. The courses of instruction will be arranged to suit the requirements of (1) persons who are training to become technical teachers; (2) persons who are preparing to enter some industrial or professional career; (3) persons who desire to attend special courses, with the view of acquainting themselves with the scientific principles underlying their work. Students intending to go through the complete course of technical instruction with the view of subse-

quently obtaining a diploma, will be required to pass an entrance or matriculation examination, which will include mathematics, pure and applied, chemistry, physics, drawing, and French or German. On the results of the examination the following scholarships will be awarded to students who are prepared to attend the complete course of instruction in any one department, provided that the merits and circumstances of the candidate justify the Committee in making the award:—(1) The Clothworkers' Scholarship of 60*l.* a year, tenable for two years and renewable for a third year, entitling the successful candidate to free education. (2) The Siemens Scholarship of 50 a year for three years, founded by Lady Siemens in memory of her husband, the late Sir William Siemens, LL.D., F.R.S. This Scholarship will be competed for in October 1885. (3) The Royal Albany Scholarship of 50*l.* a year for three years, founded by the Corporation of London in memory of the late Prince Leopold, Duke of Albany. (4) Two Mitchell Scholarships of 30*l.* a year for two years, one with and one without free education, to be awarded to candidates who have attended a public elementary school within the City of London, or whose parents are or have been resident or engaged in some trade or occupation within the City of London. The Siemens Medal, founded by Lady Siemens in memory of her husband, the late Sir William Siemens, LL.D., F.R.S., will be annually awarded to the student of greatest merit in the department of electrical engineering. The professors in charge of the several departments are:—Chemistry, Prof. H. E. Armstrong, Ph.D., F.R.S.; Engineering, Prof. W. C. Unwin, B.Sc., M.Inst.C.E.; Mechanics and Mathematics, Prof. O. Henrici, Ph.D., F.R.S. Physics, Prof. W. E. Ayrton, F.R.S., A.M.Inst.C.E.

THE Paris *Journal Officiel* announces the formation of Commission to investigate all matters connected with mines and mining in Tonquin and Annam. It is composed of various officials of experience in Indo-China, and their instructions are to draw up the programme of work to be executed by the mining party which is about to be sent out from France, and to draw up a draft agreement regulating the management and working of mines in conformity with the treaty of June last with Annam.

A SUBJECT which, according to the *Japan Mail*, is engaging the attention of native scientific men in Japan is the method of translating or transferring into Japanese the technical terms of European science. Hitherto Chinese words and characters have been employed for this purpose; in many cases the translations existed, we believe, in Chinese, and were simply adopted by the Japanese—such as the equivalents for telegraph and railway appliances, but in the great majority of cases a process of manufacture had to be resorted to. Given the sound of the technical term and its meaning, the problem was to find among existing Chinese characters one, two, or three, which suited one or other of these best; and thus a new word was formed. The scientific journal of Tokio attacks this system, saying that, whatever may be said on the score of the unity and adaptability of Chinese in transcribing technical terms, the clumsy and complex graphic system renders it unsuitable for youthful students, as the difficulty of committing to memory so many hundreds or thousands of arbitrary characters is still greater than the pursuit of a scientific or technical course of study. Prof. Yatabe, of the Tokio University, lays special stress on the use of the original foreign technical terms, instead of translating them into Chinese. In a lecture on the subject, this gentleman told the pupils of a normal school near Tokio that, in order to comprehend the scientific achievements of Europe, it was necessary to be conversant with one or more European languages, for, seen through the medium of the Chinese tongue, science lost much of its simplicity, and was at best but clumsily reproduced. Another native Professor of the University argued in a similar strain. The knowledge of some European language was, he said, essential, not only on account of the closer relations now existing between Japan and the West, but also because the study of the technical sciences would thereby be made materially easier than at present. Whatever might be the use of Chinese as a philosophical language, it was certainly most unsatisfactory as a vehicle for the reproduction of Western sciences.

M. F. A. FOREL communicates to the *Journal Suisse* an interesting account of the discovery of the relics of the "Hôtel des Neuchâtelois," an extemporised fastness on the glacier of the Lower Aar, occupied by Agassiz and his scientific friends from 1840 to 1843, while they were investigating the theory of glaciers and the Glacial period in the immediate factory of glaciers. Herr Ritter, from Leipzig, recently on a tour through the region of the Unteraar, found there a block of stone bearing the names of Stengel, Otz, and Martins, with the dates 1844 and 1845. In 1840 Agassiz and his friends, coming across an enormous block of micaceous schist, supported by other rocks, and forming a natural shelter, on the median moraine of the glacier, at the junction of the Lauteraar and Finsteraar, proceeded to complete the cabin thus prepared for them by running up some walls of dry stones. In his "Excursions et Séjours dans les Alpes," Desor gives a lively picture of the enthusiastic scientific life led by Agassiz and his zealous fellow-students of Nature in that simple yet elevated hall of science to which they gave the name of Hôtel des Neuchâtelois during the three years 1840 to 1843. The block, naturally friable, showed, as early as 1841, numerous fissures, and in 1844 split into two pieces. Since then the frost has rent it up into a heap of debris, and it is three pieces of this which have just been identified. They are a blackish micaceous schist of very fine grain. The piece highest situated bears several inscriptions of the colour of minium, but these are mostly illegible, and M. Forel could only make out "1848" thrice repeated, and "Vogt," the present Professor at Geneva; 23 m. lower down is the stone discovered by Herr Ritter, bearing in very legible capitals the inscriptions "STENGEL" (student of engineering under Osterwald), "1844"; "OTZ" (Engineer at Neuchâtel), "1845"; "CH. MARTINS" (Professor at Montpelier), with other letters which are indecipherable. There is also to be read on it "No. 2," a mark which confirms M. Forel's conclusion as to the connection of the stone with the Hotel, Agassiz having caused certain stones to be distinguished by certain numbers, and their position to be taken by Engineer Wild, the block of the Hôtel der Neuchâtel being distinguished by the number "2"; 55 m. lower still is the third stone with the inscription: "SOLIOZ AUGUSTE, 1842; LIEUTENANT GUNTREN," and a few more words hardly comprehensible. These three blocks are now no longer, as in 1840, at the summit of the moraine, but have been slipping down the incline on the side of the Lauteraar, which merges in the glacial ravine, watered by a beautiful stream. Comparing the position of the Hôtel des Neuchâtelois, as given by Agassiz (797 m. from the promontory of Abschwung), and as seen in Wild and Stengel's beautiful map of the glacier on the scale of 1 : 10,000, with the position which it now occupies, M. Forel calculates that the block must have glided a distance of 2400 m. from 1840 to 1884, or 55 m. a year. For the easier identification of the three blocks of stone by later explorers, M. Forel has inscribed on them, in fresh red colour, his own name and that of Herr Ritter, with the date 1884.

THE Institution of Civil Engineers send us the lengthy and valuable memoir of the late Sir William Siemens, presented to the Institution by Dr. William Pole. After a few words on the incidents of his life, Dr. Pole abandons any attempt at chronological arrangement as impossible because of Sir William Siemens's 'extraordinary faculty of devoting his attention to many different

lines of thought, and many different subjects of investigation, at one and the same period"; and accordingly his labours are classified under these heads:—(1) Heat and its applications, particularly to metallurgy; (2) Electrical science and practice; and (3) Miscellaneous engineering, mechanical, and scientific matters not included under the former heads. Dr. Pole then goes over the whole of Sir William Siemens's scientific labours in these fields, and, as might have been expected, produces the fullest and most valuable memoir of this distinguished member of "the creators of the age of steel" which has yet appeared.

THE "Year-Book of the Scientific and Learned Societies of Great Britain and Ireland," published by Messrs. Griffin and Co., will be found useful, and doubtless will be improved from year to year. The societies are arranged in fourteen sections, according to the field they occupy, with a fifteenth section, including some of the leading foreign societies. The compilers might certainly have avoided putting the Royal Society and the Royal Institution side by side, as if they had anything in common.

MR. W. M. MASKELL, F.R.M.S., continues his notes on the *Coccidæ* of New Zealand, and has sent us a lengthy continuation of his former papers, extracted from the *Transactions* of the New Zealand Institute, vol. xvi. That country seems to be especially rich in "scale-insects," and in Mr. Maskell they find an able student of their modes of life and characteristics. Especially curious is the species described as *Rhizococcus fossor*, the female of which does not cover herself with a sac or "scale," but sinks herself bodily in a circular pit in the substance of the leaf, and there lays her eggs; the species feeds on *Santolum cunninghamii* in the North Island. *Icenya parchasi*—a near relative of the "pou à poche blanche" (*I. sacchari*), so destructive in Mauritius, and which has probably been introduced into Queensland and elsewhere—seems to be spreading rapidly, and to be doing much damage, not only to cultivated trees and shrubs, but also to the native forests. Before carrying into effect the radical remedy of cutting down and destroying the infected trees, we would recommend Mr. Maskell to try an application of kerosene, which has certainly proved useful in the case of *Coccidæ* on oranges in America. The weak point of these papers consists in the extreme roughness of the plates; they may be characteristic so far as they go, but a few coarse scratches scarcely sufficiently represent hairs, neither does an open network of crossed lines indicate a solid and probably concave surface.

THE *Kavkaz* newspaper mentions a bolide that was seen on August 3 at Kazakh, in the district of Elizabethpol. It had the shape of a blue globe which broke into two globes of the same colour, and disappeared in the direction of the Caucasus Chain.

WE regret to learn of the death at Montreal, from typhoid fever, of Mr. Walter R. Browne, well known as a writer on the scientific aspects of engineering. Mr. Browne had gone to Montreal to attend the British Association meeting.

THE dangers to public health which lurk in out-of-the-way places appear inexhaustible. This time the danger comes from the matter which collects on coins which have been a long time in circulation, and to which we have already referred. M. Reinsch of Erlangen has devoted much study to this matter, and has investigated old and recent coins of all metals from all the European States. Everywhere he has found micro-organisms of Algæ and Bacteria. Scraping away the matter which accumulates in the interstices of the relief with a needle, and placing it in a drop of distilled water under a microscope of 250 to 300 diameters, he found fragments of textile fibres, numerous starchy granules, especially of the starch of wheat, globules of grease, some unicellular Algæ, &c. But when a microscope of greater power was used Bacteria were found among this detritus. There were long Bacteria with a vibratory or spiral movement, as well as those of a globular shape. Sometimes both forms were found on one coin; but as a rule each form was found separately. When a little glycerine or iodine was introduced into the preparation these ceased their movements. Among the Algæ two kinds were of most frequent occurrence, viz. a small *Chroococcus* and a small unicellular one resembling the *Palmellis*. They were collected in little spherical colonies of four, eight, or a dozen at a time, and were found only on old coins; recent ones contained only the Bacteria. A recent writer in *Science et Nature* refers to this discovery as of great importance from a hygienic point of view.

AT numerous places in Lower Austria several shocks of earthquake were felt on Tuesday last week. The duration of the shocks was from four to nine seconds each.

AT the last meeting of the Seismological Society of Japan, a paper (which is printed in the *Japan Gazette*) was read by Mr. E. Knipping on the meteorology of Japan. It was based on data obtained from twenty-three meteorological stations in Japan during the year 1883, the extreme positions being Kagoshima and Nagasaki in the south, and Sapporo and Nemoro in Yezo in the north. Interesting comparisons are instituted between the variations in temperature and pressure at different times of the year and in different parts of Japan, and similar variations in Europe.

THE additions to the Zoological Society's Gardens during the past week include two Ring-tailed Lemurs (*Lemur catta* ♂ ♀) from Madagascar, presented by Mr. Charles Stewart; a Common Marmoset (*Hapale jacchus*) from Brazil, presented by Mr. J. Henderson; two Peba Armadillos (*Tatusia peba*) from South America, presented by Mr. Frank Parish, F.Z.S.; a Wood Owl (*Syrnium aluco*), British, presented by Mr. J. Baldwin; two Smooth Snakes (*Coronella lævis*) from Hampshire, presented by Mr. W. H. B. Pain; seven Common Crowned Pigeons (*Goura coronata*) from New Guinea, a Victoria Crowned Pigeon (*Goura victoriæ*) from the Island of Jobie, two Brazilian Hangnests (*Icterus jamaicai*) from Brazil, deposited; a Gray-cheeked Monkey (*Cercocebus albigena*) from West Africa, purchased; a Prairie Wolf (*Canis latrans*) from Kansas, U.S.A., received on approval; a Vulpine Phalanger (*Phalangista vulpina*), born in the Gardens.

GEOGRAPHICAL NOTES

THE present number of the *Bulletin de la Société de Géographie* commences with a paper by M. Duveyrier, on the geographical extent of the Mussulman confraternity of Senousi. This sect, which is distinguished by its au tere and fanatical tenets, arose forty-six years ago under an Algerian, and appears to have in a greater or less degree permeated the Mohammedan world, and acquired vast political importance. It flourishes especially in Northern Africa, reaching as far south as Timbuctoo. The details of its precise extent and the nature of its activity are given in the paper. The second paper, which is not signed, records a French hydrographical mission to the coast of Morocco by the French officer M. Vincendon-Dumoulin in 1854. The most interesting part of the paper is the introduction, in which the writer discusses the necessity of having a dictionary of geographical etymology; that is, a work which will explain as far as possible the origin and meaning of geographical names, not only from a philological but also an historical point of view. The names, he says, which, for example, Stanley and De Brazza are giving their settlements in Africa, are explicable now, when everybody knows why Leopoldville is so called; but it may be different fifty years hence. But who knows, he inquires, that the territory called Adélie in the Polar Ocean was so called after the wife of Admiral Dumont d'Urville, or that the capes known as Jagersschmidt and Cotelle were named after the members of the hydrographical expedition to Morocco, which the paper then goes on to describe? From the report of a Committee of the Society appointed for the purpose, we see that three

gold medals for geographical work have been awarded this year. The first was granted to M. Alphonse Milne-Edwards for his submarine investigations; the second to M. Thouar for his journey to the Grand Chaco in search of the survivors of the Crevaux Mission; and the third to M. Charnay for his explorations and archæological discoveries in Yucatan. The last paper in the number is composed of a series of extracts from the letters of Abbé Desgodins on the boundary region between Thibet, Burmah, Assam, and China.

THE Danish gunboat *Fylla* returned from the Arctic regions to Orkney last week, having been sent out by the Danish Government on an exploring and surveying expedition. She has had a most satisfactory voyage, occupying nearly four months, and extending along the whole coast of Greenland to 70° N. lat. Her work included a scientific exploration of the inland glaciers in that country, and dredging, trawling, and meteorological observations there and in Davis Straits, Baffin's Bay, and Disco Bay. Many hitherto unknown specimens were brought up by the dredging, the greatest depth being 900 fathoms. Valuable collections have been brought home by the ship in all the scientific sections. The members of the expedition speak in high terms of their collections, which include a meteoric stone estimated to weigh about 2000 lb.

LIEUT. GREELY, in connection with his paper at the British Association, took occasion to say that the fact that had surprised him was the discovery that when the tide was flowing from the North Pole it was found by his observations that the water was warmer than when flowing in the opposite direction. He took trouble to have an elaborate set of observations showing this wonderful phenomenon prepared, which would be eventually published. To him the peculiarities were unexplainable.

A CORRESPONDENT of the *Standard* writes:—"On July 26 the lighthouse-keeper at Cape Reykjanes, the south-west point of Iceland, on scanning the sea with his glass, saw what he at first took for a very large ship, but which a closer inspection showed to be a new island. It had the form of a rounded flattened cone, was of considerable size, and lay, according to his estimate, about fourteen miles north-west of the volcanic island Eldey, or the Mealsack (Melsekken), which lies eight miles off Reykjanes to the south-west. Several earthquake shocks had been felt during the preceding days, and they have since occurred at intervals, but no other volcanic manifestations heralded or attended the rise of the island from the deep. Owing to the danger of approaching the island in an open boat, no one has as yet attempted to land on it. The light-keeper has observed it from day to day when not prevented by foggy weather, and reports no change in its appearance save that a large part of one side of the cone appears to have slipped or fallen down into the sea. From time to time since the colonisation of Iceland, volcanic islands have sprung up out of the waves in the neighbourhood of Reykjanes, only to disappear again after a brief period. In the end of last century an island arose at or near the same place as the present one occupies, and was taken possession of by the Danes, under the name of Nyœ (New Island), but as it consisted only of loose volcanic ash and pumice the action of the waves speedily broke it down, and after little more than a month it disappeared as mysteriously as it had arisen."

OUR ASTRONOMICAL COLUMN

VARIABLE STARS.—Several papers upon these interesting objects have lately appeared in the publications of scientific bodies:—

(1) "A Catalogue of known Variable Stars, with Notes," by Mr. J. E. Gore, in the *Proceedings* of the Royal Irish Academy, vol. iv. Mr. Gore has brought together particulars relating to about 190 stars, including their positions for 1880, the limits of magnitude, mean periods, and epochs of maximum and minimum, for the most part taken from Schonfeld's Catalogue of 1875; indeed, this Catalogue is the source of much of the information contained in Mr. Gore's paper. His summary will be very useful to those who are entering upon the study of the variable stars; some corrections are needed, but they are not of very much importance. Observations by himself of several of the stars are added in the notes following the Catalogue, and others by various observers made since Schönfeld's last Catalogue was published. The positions as printed have a lame appearance, from being given to seconds of time in right ascension and to seconds in declination: if the right ascension of an object is assigned to the nearest second of time, the more legitimate expression of the declination is to the nearest tenth of a minute. The reference to the fancied identity of "the Biblical star of the Magi" with Tycho's celebrated star of 1572 seems out of place.

(2) "Recent Observations of Variable Stars," presented by Prof. Pickering to the American Academy of Arts and Sciences. The author had previously issued a pamphlet and a circular from the Harvard College Observatory, in the hope of promoting a more systematic observation of the variable stars, and in response has received communications from a number of observers who have expressed their willingness to join in his scheme of observations. In the paper in question Prof. Pickering has brought together the results of observations of variable stars for 1883, so far as he had them at hand, to show the nature of the information which he desires to obtain in order to be in a position to issue a further circular early in 1885. It should be mentioned that Mr. S. C. Chandler is preparing a bibliography of the variables, which will eventually furnish the means of forming a catalogue of all the stars now known to be in a state of change, to a much more reliable extent than hitherto; such a work cannot fail to be of vast assistance to any one desirous of looking up the history of particular stars, which is now an operation attended with much trouble and uncertainty. With regard to his next circular, Prof. Pickering hopes that observers of variable stars, whether professional or amateur, will be generally disposed to furnish information on the following subjects—(*a*) the method of observation, if photometric, some account of the instrument, and the manner of using it; if not photometric, whether the observations are made by Argelander's method, or by direct estimation of magnitude; (*b*) stars observed in 1884, with the number of nights on which each was observed; (*c*) the time and form of publication contemplated by the observer; (*d*) plans for 1885, naming the stars selected and the number of nights on which it is proposed to observe them. This information it is desired to receive at Harvard College Observatory by February 1, 1885, as well as any material which may be useful towards making the table for 1883 more complete. Prof. Pickering's first table gives the positions of the variable stars for 1875, with the limits of magnitude and the periods; also the discoverer and year of discovery, with references to observations made in the years 1880-83. In a second table is a list of suspected variables extracted from Mr. Chandler's unpublished catalogue.

3. The Rev. T. E. Espin publishes in the *Transactions* of the Liverpool Astronomical Society "A Catalogue of the Magnitudes of 500 Stars in Auriga, Gemini, and Leo Minor," which have been determined from photographs taken by means of the equatorial stellar camera at the Society's Observatory. The apparatus was placed at the disposal of the Society by Mr. Howard Grubb. The magnitudes determined from the photographs are entirely based on those of Argelander. It is stated that the deduced magnitudes of 341 stars out of the 500 agree within 0·4 m. with those of Argelander, while in twenty-five cases the differences exceed a whole magnitude. The nebulæ M 35 and 51 have been photographed after exposures of 2h. 55m. and 2h. 0m. respectively, as also the cluster Præsepe, of which the photographs show the smallest of Argelander's stars, and some which do not occur in the *Durchmusterung*. Two stars are noted as presenting indications of variability: viz. 41°, 1222 in Auriga, which was 8·6 m. on March 10, but was not found on a plate taken a few nights afterwards; and 33°, 1895 in Leo Minor. Mr. Espin concludes with the remark, "The difficulty of reducing the stars to Argelander's scale is complicated, from the fact that near the *minimum visibile* the bluer stars alone are photographed, the yellowish ones disappearing."

COMET 1884 *b* (BARNARD).—The following positions for Berlin midnight have been calculated by Herr Stechert from his elements (NATURE, p. 431).

	R.A. h. m.	Decl. ° ′	Distance from Earth	Light
Sept. 15	19 21·4	−29 23	0·703	0·76

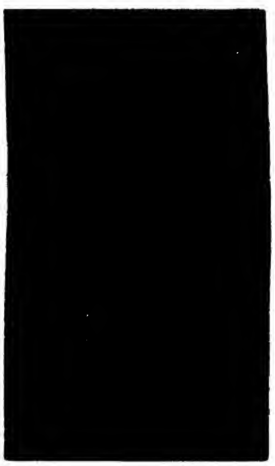
27	20 6·7	−25 8	0·792	0·55

THE MOVEMENTS OF THE EARTH[1]

VI.

WE have now to consider some of the results of these Movements of the Earth—first round its own axis, its rotation; then round the sun, its revolution—which we have been considering, results to which of course a general interest attaches, and which there will be no difficulty in showing are of very great importance to us. Occasion was taken to point out that the different appearance presented by the sun and the stars was simply due to the fact that the sun was very near to us whilst the stars were very distant, the one, a sun which happens to be near to us, the others, also suns, but happening to be very far removed from us. Now suppose we have a globe in which we have an electric light, to represent the sun, and a little globe to represent the earth, then it will be obvious that that part of the earth which is turned towards the lamp will be bathed in light, while that half which is turned from it will be in darkness, being, so to speak, only under the light of the distant stars. This shows us the reason for that great difference which we call day and night, and we can quite understand how it is that we get the apparent rise of the sun which occurs when the part of the globe on which we live is carried from the darkness into the light, and sunset which of course occurs when the globe is being carried by its rotation from the light into the darkness. This phenomenon of day and night is thus one of the most obvious results of the rotatory movement of the earth, and one which might have been dismissed in two words had we so chosen, but we will dwell upon it for a few moments, because this fundamental difference between day and night furnishes us with a reason why we should discard that sidereal time to which up to the present reference has alone been made.



49.—Diagram showing how the difference between the lengths of the sidereal and mean day arises.

Fig. 49 will show how it is that under the circumstances in which we thus find ourselves, a new kind of time must take the place of sidereal time. In this diagram we have the earth represented at two positions in its orbit, 1 and 2. It travels in this orbit in the direction of the arrows, rotating on its axis the while in the direction also indicated by arrows. Now let us consider the start-point 1, and suppose that when the earth occupies this position a particular star is on the meridian at midnight. The earth it will be remembered rotates in twenty-four sidereal hours; it will therefore take twelve hours to turn half round, so that if we consider the sun to be directly opposite the star which is south at midnight it is obvious that they are twelve hours apart. Now consider the earth at position 2. Then remembering this fundamental fact, that the distance of the stars is so enormous that a string stretched from the observer to the star at one point of the earth's orbit would be practically parallel to a string stretched to the same star from any other part of the orbit; it is obvious that the star will have the same right ascension in both positions of the earth, and the line pointing to the star will be practically in the same direction. But the sun will no longer lie along the prolongation of the line joining earth and star as it did at 1, for in consequence of the earth's revolution round the sun we shall get a gradually increasing angle as the earth in its orbital course gets farther and farther from its initial position at 1. Now it is obvious if we are going to have our time regulated by the sun instead of by the stars—and that is what we must do for the purposes of civil life—we shall have to arrange our clock so that when we pass from 1 to 2 it must, if it showed 12 o'clock when the sun was due south in the former position, show 12 o'clock also when the sun is due south in the latter position. If this be so, and we have this angle made by the line joining sun and earth and star, we shall have to make our sun-clock go more slowly than our sidereal clock, for the reason that the sidereal clock will have gone round once in less time than the earth will have got round to the same place with regard to the sun. But if we choose, and we do choose, to say that we will have twenty-four hours from sun-southing to sun-southing, then these twenty-four hours and necessarily also their minutes and seconds, will be longer than the hours, minutes, and seconds of sidereal time. Let us take another illustration. Consider the case of the earth in three different positions, represented by three globes round a central lamp. Then suppose that in each of these globes a wire is put to represent the direction in which the transit instrument points at Greenwich when the same star is observed at three consecutive intervals of twenty-four hours of sidereal time. These three wires should therefore be placed parallel to each other. Now let us take the electric lamp to represent the sun, then we shall find that, when the transit instrument on each of the earths

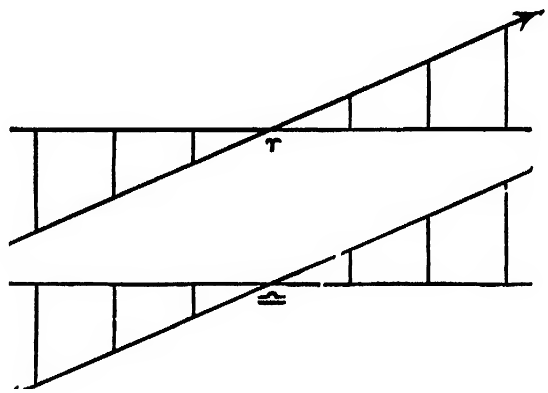


FIG. 50.—Diagram showing how the sun's apparent motion along the inclined lines representing the ecliptic in the direction indicated by the arrow-heads is represented by a smaller amount when referred to the earth's equator (the horizontal lines in the figure) at the spring (♈) and autumn (♎) equinoxes.

is brought round to point at the sun, the three wires which represent the instruments will not be parallel to each other but at some angle. At first sight it might seem that we could easily get a sun-time to replace the star-time, but unfortunately when we go a little deeper into it we find, as we often do in other cases, that it is not quite so easy—and for two reasons. We found, it will be remembered, when we came to consider the form of the earth's orbit, that it was not quite circular, that it was in fact what is called an ellipse, and that the radius vector, *i.e.* the imaginary line joining the centres of the sun and earth did not sweep through equal *arcs* in equal times but through equal *areas*, so that, if we want to invent a clock which will show twenty-four hours from the time of sun-southing one day to the time of sun-southing the next, that clock will require to be regulated differently for every day in the year, because the greater or less part of its orbit moved over by the earth will cause the greater or less angle between the lines joining sun, earth, and star.

That I hope is clear. Thus then there is good reason why this arrangement of having a sun-time from noon to noon will not work. We should have to regulate our clock for every day in the year, or rather for every two opposite days. But there is another matter. We are now in full presence of the fact that the equator of the earth is inclined at an angle of about 23½° to the plane of the ecliptic. Fig. 50 will perhaps enable us to understand this matter more easily. Let the horizontal lines represent the plane of the equator and the inclined lines the

[1] Continued from p. 256.

plane of the ecliptic. Now our clock and all measurements of time must depend upon the earth's rotation, the plane of which always remains parallel to itself, and we have seen that our start-point for geocentric and heliocentric longitude depended upon the fact that at a certain point in its revolution the earth passed through a node, and that the node at which the sun with its apparent motion crossed the equator northward was called the ascending node. In the diagram this is represented by ♈ in the upper figure, and the descending node is indicated by ♎ in the lower figure. It will be seen that if we have equal intervals along the ecliptic the motion along the equator is represented by bases of successive triangles, of which the hypothenuses lie along the ecliptic. Now the hypothenuse must be

FIG. 51.—Diagram showing how the sun's apparent motion along the ecliptic, now parallel with the earth's equator (the central line of the figure) at the summer (♋) and winter (♑) solstices, is represented by equal intervals along the equator.

greater than the base, so that we have at the ascending node the motion of a body along the ecliptic represented only by the base of a triangle of which the motion itself represents the hypothenuse; and the same thing happens in the opposite manner at the descending node; whereas if we take the other positions shown in Fig. 51, for a short time at all events the motion will be parallel, and motion along the ecliptic will be represented by an equal amount along the equator.

These then are the difficulties we have to face when we come to fix our sun-time, first, the unequal velocity of the earth round the sun; and secondly, those variations which are brought about by the fact that the two motions of the earth—its axial rotation and yearly revolution—take place in different planes. How are these difficulties got over? They are got over by pretending a sun, as a child would say. Astronomers pretend that there is a sun moving along the equator, or, in other words, they pretend that the earth's movement of revolution takes place in the same plane as its movement of rotation. It is further imagined that this imaginary sun travels at precisely that rate which it would if the average of all its rates along the ecliptic during a year were taken, so that we get something like this (see Fig. 52); first of all we have the curve B B B B, which shows the variation which would take place providing we only had to deal with the obliquity of the ecliptic. Where that curve crosses the horizontal line, we get at those moments (if we disregard the elliptic motion) the same time shown by the mean sun as we should get if the true sun had been taken; it will be seen this occurs four times during the year—on March 20, June 21, September 23, and December 22. Then there is another curve, C C C C, which represents another relation between the mean sun and the true sun. Providing that the two planes were coincident, and that the movement of the earth under these conditions were exactly the same as under the present conditions, namely, that she moved in an ellipse and that the radius vector swept over equal areas in equal times, then we should have the true and mean sun coincident on December 31 and July 1 only. Then the algebraic mean of these two curves, B B B B and C C C C, is taken, and we get as a result the lower curve D D D D, which is a compound of the two other curves, and as the result it will be seen that where we got the curve C, giving us a difference of nearly five minutes, and the curve B, giving a difference of about nine minutes in the same direction, we have a very great departure between the motions of the real and mean suns. Above and below the datum line, which is marked zero, we have 5, 10, and 15, which represent the difference in minutes at which the southings of our real and fictitious suns really take place. Early in the month of February we have a difference of very nearly fifteen minutes between the two suns, and it is at this time of the year of course that the sun dial is most in error. At other points where the effect of curve B is to cause a great difference, the effect of curve C will be to minimise that difference, and so in the compound curve D the difference is very slight. About the middle of June we get them together, then towards the end of July we get another separation, and about November 1 we come

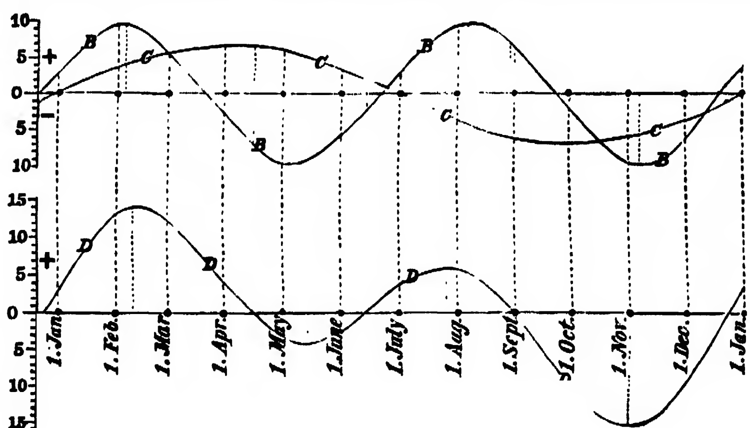

FIG. 52.—Diagram showing how the equation of time (curve D D D D) results rom the combination of curve B B B B representing the vairation due to the obliquity of the ecliptic, and curve C C C C representing the difference between the mean and true suns.

to another difference even greater than that in February. In this way a correction has been introduced, which is known as the "equation of time," and this added to the motion of the true sun, or added to that of our imaginary sun, brings them together, and by this means the mean sun is kept as nearly as possible to the average position of the true sun throughout the year. Another diagram (Fig. 53) will enable us to understand some of the considerations which have brought this about. Let F represent the position of the sun in one of the foci of the ellipse, P *e* A, round which the earth is supposed to be travelling. Now while we have the real radius vector going from F to *e*, with its unequal motion along the orbit, we have a fictitious radius vector going with absolute constancy along the circle. We get what is called the true anomaly in the angle P F *e*, and the mean anomaly in P F *e'*, and the difference *e* F *e'* is called the equation of the centre. This equation helps us to determine those curves to which reference has been made, and the chief object in calling attention to this diagram is to explain the meaning of the term anomalistic year, which it will be necessary to introduce presently. It has already been said that it is imperative, if we are to gain any advantage from it, that real sun-time and apparent sun-time should never be widely separated, because if so we might have

contented ourselves simply with sidereal time, which would have at least the advantage of being constant, so that it is most necessary if any benefit is to be derived from this mean sun of ours that it should not differ very much from the true sun. The longitude of our mean sun is therefore made equal to the mean longitude of the true sun. This having been premised, the terms "mean time" and "mean noon" will now be clear without any explanation. "Greenwich mean time" of course means time referred to the meridian of Greenwich.

We thus finally discard our sidereal time, and replace it by mean solar time so arranged that the maximum departure of this from true solar time shall be fifteen minutes in the month of February and fifteen minutes at the beginning of November. We have seen that the sidereal day is shorter than a solar day, and that consequently the hours, minutes, and seconds which

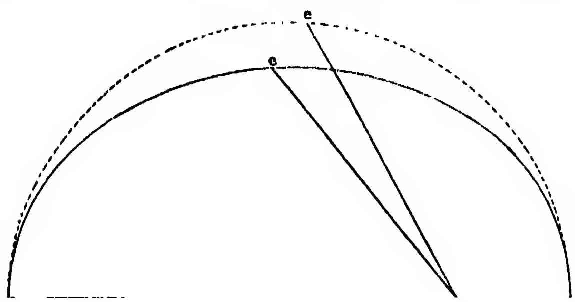

FIG. 53.—Diagram explaining mean anomaly and true anomaly.

make up the sidereal day must be shorter than those which form the solar day. The relation between the seconds of solar and sidereal time may be thus shown.

One sidereal second = ·9973 of a mean time second.
One mean-time second = 1·0027 of a sidereal second.

We have now got the results of the earth's revolution combined with its rotation, so far as day and night, considered in their more general aspects, are concerned; but we have not done with day and night yet. When we were considering the question of the inclination of the earth's axis, we went so far as to say that it was inclined $23\frac{1}{2}°$ to the plane of the ecliptic, and that it always remained practically parallel to itself. Now suppose we arrange four globes in a circle, to represent the earth in different parts of its orbit, and we have in the centre an electric lamp to represent the sun. Then, if the earth's axis is thus inclined to its path round the sun, and always remains parallel to itself, it will be seen that at one position the north pole will be all in the light of the electric lamp (which represents the sun) during the entire revolution of the earth on its axis. At the point opposite this the reverse happens, for during the entire rotation of the earth the north pole will be in the dark. At the two remaining points the pole will be just on the boundary of light and darkness. We need not consider the case of the south pole; there exactly the reverse will happen to what occurs at the north pole—when the north pole is always in the light, the south pole will be always in the dark, and *vice versâ*, as may be seen by looking at the globes. Now it should be clear that the fact of the earth's axis being inclined to its path causes different lengths of day and night throughout the year. It is simply that, and nothing else. At the poles, which, as we have seen, are sometimes entirely in the light and sometimes altogether in the dark, there will be six months of this light and six months of darkness. At the equator it will be readily understood the days and nights will be of twelve hours' duration at whatever part of her orbit the earth may be. If you take those positions of the earth where the boundary of light and darkness passes through both the poles, it is perfectly clear that the days and nights are of equal length all over the world, and a line drawn from those points through the sun is therefore called the "line of equinoxes." These points are respectively at the ascending and descending nodes of the orbit. The two other points where the North Pole is most in the light or in the dark during the whole of a rotation are known as the solstices, because it is at these times that the sun for some days appears to attain the same height at noon.

To sum up then, it will be seen that the earth's rotation and the earth's revolution, in conjunction with the important fact of the non-coincidence of the planes in which they take place, give us not only our days and our nights, but cause the lengths of them in different latitudes to vary throughout the year. We have in this inclination of these planes to each other, too, the cause of the seasons, because when the northern hemisphere of the earth has been for a long time in that position with the sun longest above the horizon, the temperature will be very different to what it is when the earth is in the other position. In the former position we have summer in the northern hemisphere, in the latter winter. The conditions of life at two such points in the orbit will be vastly different. At the equator, where the days and nights are always of equal length, the course of nature will be very uniform. As the equator is receded from and the poles are approached, this uniformity begins to disappear until, as has been said, at the pole six months of perpetual daylight alternate with six months when there is no sun.

But even now when we have got our day and our year, we have not got all.

It must next be pointed out that, whilst the axis of the earth may be said to remain practically parallel to itself, yet that it does not absolutely remain so.

As a result of this and of the earth's movement round the sun, we get a very important outcome. Although the consideration of the dimensions of the earth has scarcely come within our subject, yet the earth's rotation may be used to bring in the dimensions of the body on which we dwell in just the same way as the velocity of light was used to refer to the dimensions of its orbit.

FIG. 54.—The attraction of the sun on the earth's equatorial protuberance.

We need not, however, consider the question in detail, but we may state that the earth is a globe of something like 8000 miles in diameter, the equatorial diameter being longer than the diameter from pole to pole by some twenty-six miles, so that we have, as it were, round the equator a ring of matter some thirteen miles thick and eight thousand in diameter. Now this ring of matter, this equatorial protuberance, is presented to the sun at an angle to the line joining the centres of the sun and earth, as shown in Fig. 54, and the sun's attraction upon it can be resolved into two forces, one parallel to the line joining the centres of the sun and earth, and the other at right angles to this direction; and if we consider what will be the effect of this latter force upon such a ring, we can easily understand that it will result in an alteration of the inclination of the ring. In an arrangement for showing the effect of this attraction, the ring of matter on which the sun acts may be represented by an iron ring attached to a spinning top, and the resolved portion of the sun's pull may be imitated by the attraction of a magnet held in a nearly vertical position. As the ring rotates, the attraction of the magnet draws the ring out of the horizontal, and the poles revolves in a circle. This is what takes place with the earth's axis; hence it is not true to say that it always remains parallel to itself. This revolution is always slowly going on, being completed in a period of about 25,000 of our years. In consequence of this motion, what happens is this: the line of equinoxes which is at right angles to the line of solstices is constantly changing its position along the earth's orbit, producing what is called the precession of

the equinoxes. We have to consider, therefore, not merely the sidereal year, the time between which the earth is at one point with reference to the sun and a star, and the time when it is at that same point again; we have not merely to consider the fact that this line of solstices, with its conjoined line of equinoxes, varies with regard to what is called the apse line, that is, the line joining the perihelion and aphelion points of the orbit, or the axis-major of the ellipse—but we get from this another year which is called the tropical year, which, like our mean time, is the one most used, because it brings the year into relation with our seasons. Now that we have got our mean time and know exactly how and why we have got it, we may express the sidereal year in mean time, and say that it consists of 365·256 solar days. The tropical year—the time which elapses between two successive passages through the vernal equinox—is shorter than the sidereal one, owing to the precession along the orbit of the equinoctial points, and consist of 365·242 mean solar days, and the difference between the lengths of this and the sidereal year will of course give the annual amount of precession which takes place. Anomalistic year is the term applied to the period which elapses between two successive passages through the perihelion or aphelion points of the orbit; and as these points have a forward motion along the orbit, this year is longer than the sidereal one, being 365·259 mean solar days.

We may give the exact lengths of these years in days, hours, minutes, and seconds as follows:—

	Mean solar tim d	h.		
Mean sidereal year	365	6	9	9·6
Mean tropical year	365	5	48	46·054440
Mean anomalistic year	365	6	13	49·3

The Movements of the Earth are so important to us, and so interesting in themselves, that it is not possible in six lectures to exhaust all that may be said about them or learned from them. I trust however that I have left no point of the first importance untouched. The moral of these lectures is that astronomy has appealed to physics, and has not appealed in vain, for the demonstration of the physical reality of the movements in question.

J. NORMAN LOCKYER

THE FRENCH ASSOCIATION FOR THE PROGRESS OF SCIENCE

THIS Association began its meetings at Blois on September 3. The financial situation of the Association is very prosperous indeed; the capital has amounted to 20,000*l.*; but the sum spent in scientific researches amounts to only 300*l.*

The President of the Association for this year is M. Bouquet de la Grye, and his inaugural address consisted of a sketch of the history of oceanic hydrography. He dealt with the difficulty of the determinations made on the bottom of the sea, and insisted on a new idea of his own. He believes that the level of the sea presents considerable variations owing to the quantity of salt contained in the water. He says that the level of the Mediterranean ought not to be so high as the level of the ocean owing to the greater quantity of salt and consequently of density. A diminution of temperature produces the same effects as enlarging the density; so an increase of the temperature of the German Ocean would produce a flood on the Belgian, Dutch, German, and French coasts, and bring the sea to Paris.

Dr. Grimaux, a pupil of the late M. Wurtz, delivered a speech on the illustrious Academicians who have died during the past year, among whom Dumas and Wurtz have unquestionably the foremost place.

It is probable that this year the long-hoped-for fusion with the Association Scientifique de France, established by Leverrier, and presided over by Milne-Edwards, will take place, and the two Associations amalgamated in one will take a new start.

One of the principal objects of the present sitting has been the examination of the Thenay geological strata, where Abbé Bourgeois thinks he has discovered Tertiary man. The principal French geologists have arrived in Blois for the excursions. There are very few foreigners at the meeting.

TRAINING IN NAVAL ARCHITECTURE[1]

AT Govan, the great shipbuilding suburb of Glasgow, on the 4th inst., Prof. F. Elgar, of Glasgow University, addressed the students attending the Science and Art Classes upon the above subject. In the course of his address Prof. Elgar said:—

"All of the students who attend the classes in naval architecture and engineering here are probably much better acquainted with the practical and experimental aspects of the work they are engaged in than they are with the science which underlies it; and their present object is the very vital and praiseworthy one of acquiring such scientific and technical knowledge as will enable them to apply sound principles to the performance of their work, and to assist them in dealing intelligently and successfully with the many difficult and novel questions which are constantly obstructing and puzzling them. There are no branches of mechanical art in which sound scientific knowledge is more essential and useful, or in which it is more necessary for theory and practice to go hand-in-hand together, than those of shipbuilding and engineering. A modern steamer is so complex a machine that no attempts to construct one without calling in the aid of science in some form—either directly or by copying what others have learned by it to do—could possibly end in anything but disastrous failure. Try to imagine a man who had never heard or read of any of the teachings of science attempting to construct a modern steamship—a man who did not know even of the proposition, said to have been demonstrated by Archimedes, that a floating body displaces a volume of water whose weight is equal to its own weight; and who was ignorant of the wonderful discoveries that have been made of the laws by which heat generated by the combustion of coal is converted into mechanical work through the agencies of the boiler and steam-engine. It only requires to state the matter in this bald form in order to show how hopelessly impossible and absurd such an attempt would be, and how vitally dependent shipbuilding and engineering are upon the past achievements and present teachings of science. On the other hand, the highest scientific talent the world has yet produced would be equally unable to arrive at a successful result simply by means of pure theory, however advanced, and by strict *a priori* methods. The course you are pursuing, and which I trust you will not depart from, is the one best calculated to insure for you the greatest success in your work and advancement in your various positions in life; and as in the daily practice of your profession you are perforce kept well abreast of the practical and experimental sides of your work I would now urge you, in the strongest manner possible, to cultivate most diligently and thoroughly a knowledge of the science and of those natural laws upon which the efficiency and success of your efforts depend. Whatever may be the character of your daily work, whether you are employed as engineers, draughtsmen, or mechanics—and I am very pleased to know that there are working mechanics who attend these classes, and who are among the most earnest, intelligent, and capable of the students—never rest satisfied till you know the meaning of all that you do and why you do it. Do not be content with merely learning methods of setting off work and performing calculations, or with copying processes you may have seen others employ. The man who merely does as he sees others do, without very well comprehending why they do it, and who works strictly by rule and line, looking to custom as the supreme authority, will never improve or advance himself, nor be of much real use in such times as these; nor will he find much interest in his work.

'Custom, which all mankind to slavery brings,
That dull excuse for doing silly things.'

Never look to custom as being a sufficient authority for anything, however respectable its antiquity may have made it; but be determined to understand for yourselves whether or not it is based upon sound and intelligible principles. Although we are now meeting under the auspices of the Young Men's Christian Association, I can safely recommend you to indulge freely a spirit of scepticism in this particular department of the Association's work. The region of science and of the pure intellect is not one in which you should be content to accept the mere authority of any one as final, or to test any question except by the standard of your own reason. Do not be too eager to believe that anything you are told is correct until you are able to prove it for yourselves, and till you no longer feel any ignorance or doubt in the matter. The necessity for combining wide scientific knowledge and sound theory with practical experience, in the carrying on of shipbuilding and engineering operations, is daily becoming more and more pressing. If you tried to avoid it you could not. In this age of keen competition and rapid development, increasing demands are made upon all who are engaged in these important

[1] Communicated by Prof. Elgar.

industries. Every success that is achieved by the most advanced and sensational productions creates a demand for still further progress; and in meeting these demands, in the future, the race will be to the swift and the battle to the strong. The speed and the strength that you require in order to enable you to hold your own in this contest are speed and strength of intellect. In other words, you require your intelligence to be cultivated and well informed, and to be made prompt and active, by means of scientific culture; and it is necessary for you to acquire such a firm and comprehensive grasp of sound theoretical principles as will enable you to rely safely upon your own powers of judgment, and to act in difficult cases with certainty and precision. Not only does modern competition ever demand more from you in the way of technical knowledge, skill, and resource, but it also shortens the time at your disposal for supplying it. The huge and complicated engineering structures of the present day, such as are constructed in this district, have to be completed in as short a time as the much simpler and smaller ones of a generation ago. You have thus not only much more to think about in building a ship, and problems of greater number and difficulty to solve than used to be the case, but you have only the same time in which to do it all. You cannot afford to delay the progress of construction for the purpose of trying experiments or brooding over any difficulties you may meet with. It is necessary to decide promptly each question as it arises, and you have to qualify yourselves for doing that. The naval architect and engineer of the present day requires to supplement his practical knowledge by a close and systematic study of various branches of science. An enumeration of some of the chief of them will be sufficient to show how great are the demands thus made upon him. There are the laws upon which the flotation and stability of ships, and their behaviour among waves, depend; those which determine the structural strength of a vessel, and its relation to the forces which may be brought to bear upon her by her own weight and that of her cargo, when she is floating upon a changing wave-surface; the difficult problems connected with the resistance of a ship to motion through the water, the power requisite to drive her at a given speed, and the manner in which this is affected by her outward form and proportions. Then there is the wide field of thermal science, and its application to the means by which the conversion of heat into mechanical work is effected through the agencies of the boilers, cylinders, condenser, and mechanism of the engines; together with the action of the propeller, and the principles upon which its efficiency depends. No man has ever yet succeeded in completely mastering these difficult and complicated problems; and it is perhaps not possible for many of you to advance very far towards their solution. Still it must be borne in mind that it is only by studying the sciences which bear upon them that any real or substantial progress can be effected; and although finality may be unattainable, great advances are possible, and are constantly being made. Hardly a year passes without something considerable being done to improve our knowledge of those natural laws upon which the safety and efficiency of ships at sea depend. There is probably no district in this country which has benefited more in the past than Govan by scientific progress and great mechanical skill in shipbuilding and engineering, or whose prosperity in the future is more dependent upon it. Govan has been placed among the foremost of shipbuilding communities by means of great scientific and practical talent, industry, and enterprise; and it rests with many whom I now see before me to maintain it in the honourable and distinguished position to which it has been raised. The names of Napier and Elder, not to mention others, are alone sufficient to give prestige to any engineering locality; and they insure for Govan a high place in all future records of scientific, mechanical, and industrial progress. Upon you rests the responsibility of worthily walking in the footsteps of those and others among your distinguished men, and of striving to keep erect in this district the noble edifice they have reared."

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, September 1.—M. Rolland, President, in the chair.—Some remarks on the subject of the theory of the figure of the planets, by M. F. Tisserand. The author's calculations and estimates of their present form are based on the assumption that the celestial bodies were originally in the fluid state, subject only to the mutual attraction of their constituent elements, and endowed with a rotatory movement with very slight angular velocity. Their outer surface would thus be somewhat that of a revolving ellipsoid.—Researches on the general development of vegetation in an annual plant: functions of the hydrocarbon elements, by MM. Berthelot and André.—Note on the general resolution of the linear equation in matrices of any order, by Prof. Sylvester.—Remarks on the attempts made at various times to solve the problem of aërial navigation, by M. Laussedat. The author supplies a rapid sketch of the progress of aërostatics in connection with the Commission lately appointed by the Academy to examine the claims of priority of various inventors. He considers that General Meusnier was the first to introduce the elongated shape of the balloon, the screw as the propelling agent, and the principle of the "*ballonnet*" or air-bag, rediscovered by M. Dupuy de Lôme. M. Conté is credited with great improvements in the construction of spherical balloons, and M. Alcan is stated to have anticipated M. H. Giffard by several years in the application of steam to aërial navigation.—Comparison between the coloured electro-chemical and thermal rings of Nobili and others, by M. C. Decharme.—Observations of the planet 240 discovered at the Observatory of Marseilles on August 27, 1884, by M. Borrelly.—Determination of the wave-lengths of the chief rays and bands of the infra-red solar spectrum, by M. Henri Becquerel. Tabulated results are given for the chief bands in millionths of millimetres.—Remarks on the formation and development of the nervous cellules in the spinal marrow of mammals, by M. W. Vignal.—Note on the recent luminous phenomena observed around the sun in Switzerland (second communication), by M. F. A. Forel. A second trip to the Alps, undertaken towards the end of August, enables the author to confirm and complete the details already communicated to the Academy. Aëronauts are invited to study some of these light-effects, and especially the red corona round the sun, scarcely perceptible from the plains and low elevations, but perfectly visible at altitudes of from 3000 to 6000 feet above the sea level.—Account of the optical telegraph recently established between the islands of Mauritius and Réunion, by M. Bridet. The telegraph set up on Lacroix Peak in Réunion and Vert Peak in Mauritius was completed on the night of July 12–13, when messages were freely exchanged between the two islands.

THE ZOOLOGICAL COLLECTIONS OF H.M.S. "ALERT"

Report on the Zoological Collections made in the Indo-Pacific Ocean during the Voyage of H.M.S. "Alert," 1881-82. (London: Printed by Order of the Trustees of the British Museum, 1884.)

WE need only remind our readers that the *Alert*, under the command of Capt. Sir George Nares, and his successor, Capt. J. Maclear, made a voyage of survey which lasted during the years 1878-82, that the principal parts of the survey were carried on (1) in the region of the southern extremity of the American continent; (2) in that of the coasts of North-Eastern Australia and Torres Straits; and (3) among the groups of Oceanic Islands in the Western Indian Ocean situated between Madagascar and the Seychelles. Dr. Coppinger was the surgeon on board, and it will be always to his credit that while ever attentive to his official duties he succeeded in making and sending home immense collections of marine animals taken by him at the several stations. Those collected off the South-Eastern American continent were reported on in a series of papers published in the *Proceedings* of the Zoological Society for 1881, and were presented to the British Museum. Those from the two other regions were also deposited in the British Museum and reported on by the officers of the Zoological Department, but these reports were, both in their extent and importance, far beyond the scope of any periodical publication, and at the suggestion of Dr. Günther, the Keeper of the Zoological Department, the trustees have published the full account in the form of a separate volume. Irrespective of a number of specimens set aside as duplicates, not less than 3700, referable to 1300 species, were incorporated in the national collection, and of these more than one-third were new additions, if not to science at any rate to the Museum. Well may Dr. Günther write that these "pages are by themselves a lasting testimony to the great service rendered by Dr. Coppinger to the National Museum and to the cause of science."

The exigencies of the service prevented any deep dredgings, so that though many interesting discoveries were made in the western parts of the Indian Ocean, the depths of this region are still waiting to be explored. The account of the collections made at Melanesia form the first 482 pages of this volume. The Vertebrates are reported on by Mr. Oldfield Thomas, Mr. R. Bowdler Sharpe, and Dr. Günther. They call for no special notice; but Dr. Günther takes the opportunity afforded him by the examination of several well-preserved specimens of Branchiostoma in Dr. Coppinger's collection to give a revision of the known species. While at one time inclined to agree with J. Müller that there were no specific differences between Brazilian and European specimens, and even considering specimens from Indian and Australian localities to be referable to the one species, Dr. Günther has now convinced himself that this view is incorrect, and that Sundevall was quite right in drawing attention to the number of myocommas as an excellent taxonomic character. The number can be ascertained even in specimens in an indifferent state of preservation, and varies very little; whilst the extent in depth and length of the delicate fin which surrounds the posterior part of the tail is a much less reliable character, subject to much alteration by the spirit unless great care is taken in the preservation of the specimens. The species may be briefly enumerated as (1) *B. elongatum*, Sund., Peru; (2) *B. bassanum*, G., Bass Straits; (3) *B. belcheri*, Gray, Borneo and Torres Straits; (4) *B. caribæum*, Sund., Rio de Janeiro; (5) *B. lanceolatum*, Pallas, Europe, Atlantic coast of North America; and (6) *B. cultellum*, Peters, Moreton Bay and Thursday Island. A species of this genus is common on the sandy shores of Mahé, one of the Seychelles, but does not appear to have been dredged by Dr. Coppinger.

Mr. Edgar Smith's Report on the Mollusca forms quite a monograph of this group as found in North and North-Eastern Australia: many new species are described, and most of them are figured. The Echinoderms are described by F. Jeffrey Bell. "Though there are no new Echinoidea, there are some very precious series of some species, *Marctia planulata* being notably well represented": 22 species are catalogued. Thirty-one species of Asteroidea are enumerated, 4 being new; and 26 species of Ophiuroidea, four of which are new, and a new genus, Ophiopinax, is established for *Pectinura stellata* of Lyman. Of the Holothuroidea 19 species are mentioned, and 6 are described as new, and figured. As to the Crinoidea, the author acknowledges the help he received from P. H. Carpenter, and details 27 or 28 species. "The proportion of undescribed to described species is no doubt appalling." Of 15 species of Antedon, 12 are described as new; and of 12 species of Actinometra, 4 are described as new, and 2 are recorded for the first time on the manuscript names of Herbert Carpenter, to be more particularly described in his forthcoming Report on the Comatulæ of the *Challenger*.

The Crustacea, reported on by Mr. E. J. Miers, chiefly collected "on the north-western, northern, and north-eastern coasts of Australia, are very numerous, and are interesting not only on account of the large number of new or rare species obtained, but also on account of the careful manner in which, in nearly every instance, the nature of the sea-bottom and the depth of water, &c., were recorded;" 203 species are enumerated, and 45 are described for the first time. The depths seem to have been from off shore to 30 fathoms. Eighteen plates of figures accompany this part of the Catalogue.

The collections of Alcyonaria and Sponges made by Dr. Coppinger are described by Mr. Stuart O. Ridley, whose reports are very welcome additions to our knowledge of these forms. Although not containing deep-sea forms, these collections give a good general insight into the character of the fauna of the shallow waters of the north east and north-western coasts of Australia. The almos absence of forms of Pennatulidæ—only 2 species are re corded, one very young, and the other very imperfect—is hardly to be accounted for by the fact that no greater depth than 36 fathoms was reached with the dredge, as the Pennatulids are by no means exclusively deep-sea forms. Of the fixed forms 36 species are referred to, of which 12

are described as new. The occurrence of two kinds of polyps differing chiefly in size is noted in a new species of Melitodes. The Sponge collection was large, comprising over 300 specimens, representing 110 species, besides 7 distinct varieties, of which more than half were well preserved in spirits; a large proportion—42—were new. More than one-sixth belonged to the Ceratosa, 86 to the Silicea, with no representatives of the sub-order Hexactinellida, and there were but three species of Calcarea. The author deserves great credit for the painstaking way in which he has described every form, so that no doubt might remain as to its character; and where there was the slightest doubt of the form being a new species he has refrained from possibly adding to an already over-burdened synonymy.

The description of the collections from the Western Indian Ocean forms the second part of this volume, and occupies about 150 pages. The reporters are the same as in the previous part. Among the birds, Mr. Sharpe describes a new Turtle Dove (*Turtur coppingeri*) from Glorioso Islands. Mr. Edgar Smith's list of Mollusca "may be regarded as an appendix to E. von Martens's work on the 'Mollusca of the Mauritius and the Seychelles'; of the 121 species noted, between 40 and 50 do not occur in Möbius's work, and the majority of them, as might be expected, are well-known forms." Thirteen new species are described and figured.

Forty-eight species of Echinoderms are tabulated by Mr. F. Jeffrey Bell. The only object of special interest is a remarkable new Ophiurid, for which a new genus, Neoplax, has been established; *N. ophiodes* was found at Darros Island, Amirante Group.

The collection of Crustacea, described by Mr. E. J. Miers, though less numerous in species and less interesting than those obtained on the Australian coasts, contains a large number of rare and undescribed forms, partly owing to the fact that the groups of islands known as the Amirante, Providence, and Glorioso Groups have hitherto been unknown to the carcinologist; 104 species and varieties are enumerated from the African sub-region, of which 16 species are described as new. A useful table showing the distribution of the species on the East Coast of Africa and islands adjacent is appended to this Report.

Mr. C. O. Waterhouse describes a new beetle (*Cratopus adspersus*) from Eagle Island (Amirante), and Mr. A. G. Butler a new moth (*Deiopeia lactea*) from Providence Island (Mascarines).

The series of Alcyonaria and Sponges, as before, are described by Mr. Stuart O. Ridley. The collection of Alcyonarians made was small, not, we should imagine, because the dredgings were limited to depths not exceeding 30 fathoms, but to the difficulties of collecting on and under coral reefs. Probably the same difficulty was in the way of a collection of Zoantharia being made, though notably species abound all around these Western Indian Ocean Islands. Of the 6 species of Alcyonaria, 2 are noted as new. The collection of Sponges was more important, containing as it did 56 species, of which 21 are described as new. In a survey of the species the author notes that, "notwithstanding the large proportion of new specific forms, there is a comparative scarcity of forms showing marked distinctive characters of generic importance which are not also to be found in the more familiar Atlantic fauna." Indeed this western part of the Indian Ocean may be considered, so far as the Sponge fauna goes, as transitional between Australia, South-West Africa, and the Mediterranean.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Flow of Streams

THE inclosed notes by my friend Mr. George Maw of Benthall Hall will no doubt interest some of your readers. They were communicated by me to Sir Wm. Thomson, who made the following remarks upon them:—"Mr. Maw's notes are extremely interesting. I lately observed similar phenomena in the streams flowing from the pools on the Burbo Bank near Liverpool. You ought to send them to NATURE."

DEAR MR. SMITH,—As I know you have been making observations on river currents and the effect of friction on the motion and passage of streams, I cannot resist sending you the accompanying notes on a very curious case we met with near the Lake of Thun. It is an extreme illustration of the action of gravitation and friction working, as it were in opposition. I have often observed something of the same kind before, but never so well marked. Looking up the stream from the lake, the effect was just like a long ladder of low waves approaching you, each separately breaking over a low fall into the lake.

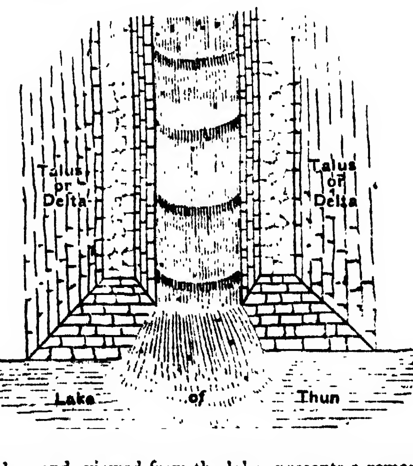
Believe me very truly yours,

GEORGE MAW

Hotel and Pension Ober, Interlaken, June 29

Notes on a Pulsating or Intermittent Stream at Merligen, on the Lake of Thun

The intermittent flow of streams familiar to us, from the rapid pulsation of the cataract to the slower rise and fall at regular intervals of less precipitous streams, is strikingly illustrated in a mountain stream flowing into the Lake of Thun, near Merligen. The lower part of its course over a small talus or sloping delta has been artificially banked up as a straight channel 15 feet wide, evenly paved and walled with stone. The lower part has an inclination of about one in twelve, and the upper part towards the mountain gorge a slope of about one in nine. It flows directly



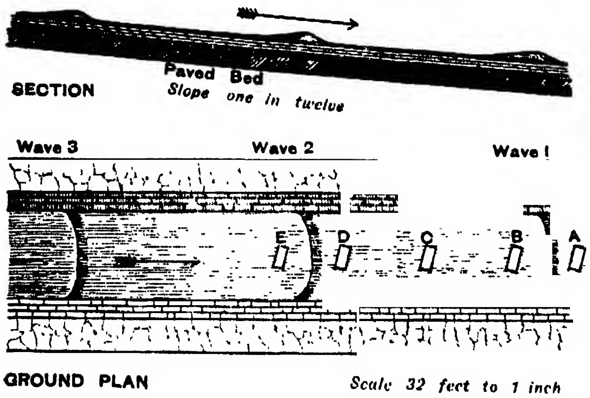
into the lake, and, viewed from the lake, presents a remarkable appearance.

The fall into the lake pulsates at intervals of $3\frac{1}{2}$ seconds by a sudden incr[illegible] of volume, and the stream above, flowing over

the level paved bed presents the appearance of a ladder of low advancing waves occurring at regular intervals of about 40 feet over the lower slope of one in twelve, and at less regular intervals of about 12 feet over the steeper slope of one in nine.

Of the motion of the stream over the lower slope of one in twelve the following particulars were noticed :—

A floating body travels at the rate of 9½ feet per second, but this does not represent the speed of any part of the water.



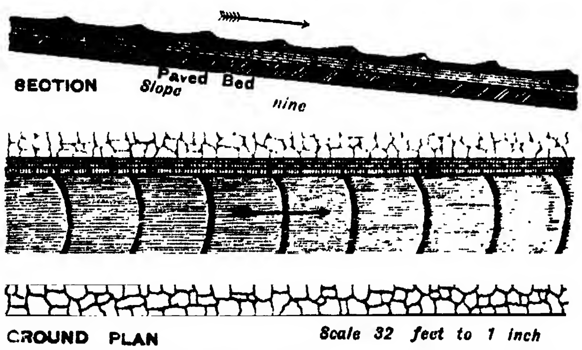
The wave-heads advanced at the rate of 13 feet a second, and the intervening stretches of stiller water (as nearly as I could judge) at about 6 feet a second. It is evident that the upper and lower currents are travelling at different rates—the bottom current retarded by friction, the surface current advanced over it by gravitation, accumulating at intervals of about 40 feet into wave-heads of a semicircular form, the sides being bent back by latent friction.

The motion of a floating body in the stream of advancing waves is very peculiar. A piece of wood thrown in at A, just in front of the advancing wave, No. 1, is *for a moment* carried forward by it, but the slower lower stratum gains the mastery, and the wave advances in front of the wood, which is successively found at B, C, D, E, &c. *relatively* to the advancing wave-heads, the floating wood recedes up the stream, though actually advancing at a rate between that of the upper and under or ground current.

The waves occur at intervals of about 40 feet, and occupy a trifle over 3 seconds in passing over the space that separates them.

Of the motion of the stream over the steeper slope of about one in nine, the following particulars were noticed :—

A floating body travels at the rate of 12¼ feet per second. The wave-heads were less clearly defined than on the less steep



incline, and it was difficult to accurately measure their rate of advance, but as in the other case they rapidly overshot a floating piece of wood. They occur at much shorter intervals (about 12 feet) than on the less steep incline. GEORGE MAW

Interlaken, June 28

I may mention that my observations referred to by Mr. Maw were made upon the current of the River Severn with a view to explain the cause why the men who navigate the barges, in descending this river by the force of the current only are enabled to steer with a moderate degree of effectiveness. The power results from the different velocities of the current at and beneath the surface. A little below the surface, roughly speaking at about one-fifth of the actual depth, the current seems to have its maximum velocity, and consequently the hull of the vessel floating down the stream is immersed in water flowing more rapidly than that at the surface, on which the rudder for the most part acts.

I was enabled to demonstrate this fact by the following simple experiment. Having noticed that leaves of trees, after lying for some time on the ground and nearly saturated with water, become almost of the same, and after a longer time of greater, specific gravity than water, it occurred to me that such leaves, while in the first-named stage, would show what I desired to know, namely, the relative velocities of the stream at different levels below its surface. Two straight bars of wood, each about thirteen or fourteen feet long, were tied together at one end, between the two the foot-stalks of a number of poplar leaves were inserted (this kind was chosen because of the length of the footstalk for insertion between the bars, and its brightness of colour rendering it more visible in the depth of the water); the bars were charged with the leaves at intervals of about three inches, and then, choosing a place where the river was of suitable depth, the bars charged with leaves were plunged into the water, the connected ends touching the ground. The water was so clear that every leaf remained visible; then I opened the ends of the bars at the surface, and was gratified by seeing every leaf floating away and preserving as to depth very nearly the same relative position. Floating with the stream in my boat, I soon saw those nearest the bottom gradually lagging behind, and still more was I gratified when, after proceeding about forty yards, the leaves that were about two feet below the surface had distanced those at the surface in an unmistakable manner by at least three feet, the current being about four feet per second. The whole series forming a curve as is here shown.

Greatly pleased with this first experiment, I was not satisfied till I had repeated it again and again, not only on that occasion, but when the wind was blowing down the river, and therefore should have accelerated the leaf at the surface, which it undoubtedly did; but only the leaf on the surface, and that to a much smaller degree than I expected, and it left unaffected all that were beneath. A calm day is the best for this experiment, because the ripple renders it difficult to see below the surface. The water must of course be clear, a condition with which we are much favoured in this river. Mr. Maw's observations of the different velocities of the pieces of wood and the wave heads are quite in harmony with mine; the depth of the water in the stream at Merligen would be only a few inches, and pieces of wood were immersed so deeply that they would be more affected by the retarded current four-fifths below than by that one-fifth at the surface. J. P. G. SMITH

Sweyney Cliff, Coalport, Shropshire

Ocean Swells

THE late melancholy accident in Fingal's Cave, Staffa, by which three lives were lost, when several visitors to the island were washed off the railed ledge by a large wave which suddenly and unexpectedly broke into the cave, leads me to submit the following account of a somewhat similar wave and on the same part of the coast.

On the 4th inst. I took a small 5-ton sailing-boat from Oban to the Island of Lismore. We had a steady south-west breeze, going there with an even slight swell in the more open part, coming up the Firth of Lorne from the Atlantic. On our return the wind dropped to a dead calm and shifted to the south-eastward, so that to get back we took to the oars, the water becoming perfectly smooth as we neared Kerrera (between 5 and half-past 5 o'clock), when, standing at the bow, and looking seaward, I was surprised to see a broad wave or long swell coming from the south-westward, followed by two minor undulations. They

passed the boat, which rose and fell to them as they swept on. Ahead was the small island near the north-west entrance to Oban Harbour; Kerrera Island was close on the right or starboard bow. The sea was so calm, there was no sign of wash on either shore. As the wave rolled in I watched it, and after a few seconds the white line of surf became visible and the noise of the same following told of its breaking on the rocks with some violence. It was not the wash of any steamer, as the boatman at first unthinkingly surmised, for in the first place it was too broad a dome of water, many of our boat's lengths, into which the few short waves even of the largest steamers could not resolve themselves; secondly, there was no steamer in sight, nor had any lately gone by, save the Duke of Argyll's steam yacht, which had passed near us more than half an hour previously.

Such a wave could not have originated in the narrow channel between Mull and the mainland, but must have come in from the Atlantic, and had its origin, I imagine, in some far distant submarine disturbance. I have seen a report in the papers of an earthquake in Jersey, and I am informed by some friends lately returned from Cornwall (near St. Michael's Mount), that on August 26, about 4 p.m., when watching a seine net being pulled ashore, a wave larger than usual—described as a long black line, seen for a long time—rolled in. Perhaps others may have noted similar waves at other parts of the coast, and been able to record the exact time. H. H. GODWIN-AUSTEN

Deepdale, Reigate, September 9

Salmon-Breeding

ON August 28 an examination was made at Lord Lauderdale's fish-rearing ponds at Howietoun into the condition of the young salmon and hybrid Salmonidæ, and with the following interesting results:—

A hybrid was taken from Pond No. 3 which measured 6·5 inches in length; it was one of about 190, all much the same size, which were raised from the eggs of the Lochleven trout fertilised from the milt of the American char, *Salmo fontinalis*, on November 15, 1882. The specimen was a male with the milt nearly fully developed; the fish would evidently have bred this winter.

A hybrid was removed from Pond No. 4 which measured 7·5 inches in length; it was one of about 90, and raised from the ova of the American char milted from a Scotch char from Loch Rannock on November 15, 1882. It also was a male with the milt as fully developed as in the preceding hybrid.

Segregation in these ponds has been most rigidly carried out, and the results show that trout and char, or two species of char, will interbreed and give fertile offspring. A few more months will decide whether the females are as forward as the males, and whether the milt itself is prolific or not so; also to what extent hybrids will interbreed.

A hybrid was removed from the Octagon Pond at Craigend which measured 6·5 inches in length; it was one of 212, and raised from the ova of the Lochleven trout, fertilised by salmon milt on December 24, 1881. It was a barren female; whether any will be fertile time will show.

A grilse was taken from the salmon pond at Howietoun which measured fourteen inches in length; there are a large number, but they are in too deep water to count. These fish were raised from the ova and milt of pure salmon taken from the Teith in December, 1880. The specimen was a female, with the ova well advanced, being 0·1 inch in diameter, and would have bred this season. This fish was well nourished, with eleven rows of scales between the adipose dorsal and the lateral line, and sixty cæcal appendages. This solves the question that our salmon may not only be reared in a healthy state in suitable ponds of fresh water, but also, if properly cared for, will breed without descending to the sea. Last year the milt of the pars from this pond were successfully used for breeding purposes.

FRANCIS DAY

Hydrodictyon in the Eastern Counties

IT may interest some of your readers to know that *Hydrodictyon utriculatum* (Roth), reckoned by Dillwyn among the rarest of the fresh-water Algæ, and now generally described as confined to the ditches and pools of the Midland and Southern Counties of England (W. J. Hooker, 1833; Harvey, 1841; Hassall, 1845; and Griffith's "Micrographical Dictionary," 1883), can again be claimed as an inhabitant of the *Eastern* Counties. A few days ago I found a fine and well-grown specimen in the river just above the well known sluice at Denver.

In the earlier half of the present century Cambridge seems to have been the centre for its distribution. Dillwyn, in 1809, relates that he received his specimen from the pool of the old Botanic Garden. Harvey, in 1841, says that he has fine specimens from Prof. Henslow, gathered in a pond in the Botanic Garden at Cambridge, where the plant has existed for many years. Hassall, in 1845, repeats Harvey's words, again on the authority of Prof. Henslow. Since that time it appears to have become completely extinct in this neighbourhood. The Curator tells me that two or three years back an attempt was made to introduce it into the pond of the new Botanic Garden, but without success. It is, I think, therefore worthy of record that this remarkable plant, so interesting to the biologist, has been lately discovered, apparently naturalised, at the bottom of the Ten Mile River, about twenty yards from the tidal waters of the Ouse.

The reappearance of Hydrodictyon on the fens round Cambridge is also interesting from the hope it inspires that, owing to the increased facilities for investigation now afforded by the University, further light may be thrown upon its singular cycle of development which, notwithstanding the labours of Areschoug, Cohn, Pringsheim, and others, must be said to be still somewhat obscure. J. C. SAUNDERS

Downing College, Cambridge, September 4

The Sky-Glows

THE sun-glow phenomena have entered upon such a fresh phase that I venture to send some extracts from my notes. It is not simply a renewal of the sunsets of last season, although that in itself will doubtless seem remarkable to those who have not noticed the almost constant occurrence of the "day glows" throughout the summer; the chief point is the radiating character.

September 11.—Glow 6.50 p.m. At 7 a vertical bar 2° to 3° across at base, to altitude 20°. Another at angle 45° to north; at 7.3 a third at angle 30° to north. The three faded at 7.5, 7.7, and 7.10.

September 12.—Sun seen to set by 6.20. At 6.35 ruddy tint above earth shadow in east; gone at 6.45. 6.50, fine glow from north-west to south-west, up to 30°; 6.55, very fine, up to 35°; much purple. Gradual change to low orange glow by 7.4, this fading by degrees, but partial return at 7.9; little left at 7.19.

September 13 (*sunrise*).—4.57 a.m., lovely orange glow and reflection in west. Cirri bright. 5.0, pink shot up vertically (in inverted pyramid) to height of Jupiter. 5.0½, bar at angle of 45° to north. 5.5, whole north-east to south east suffused, broken by dark bars, four to north, five to south, radiating from sun. Central mass now 5° to 10° above Jupiter. Cirri now dark at east, but slight tint near Venus (these proved to be higher and more feathery, the others about 7° or 8° above east by north, approaching to cirro-strati). 5.7, now five bars to north, seven to south. Light wider spread, now to level of Venus (roughly measured as 35°). Soon traces even to 45°. Bars *very* marked; one from east-north-east reaches north-north-east, at altitude about 22°. Low cirri now re-lit. 5.15, whole mass now barred; nine to north, and two new ones to south of centre, but lower part to south now gone. Cloud over Venus now re-lit. 5.20, going to west window find marked *counter-glow*, also barred, radiating from perspective just like bands of cirrus, yet marvellously clear sky. Four dark bands to south, five to north, wider than those seen in east, and definition much less distinct. Rosy tints now gone. A ruddy tinge almost from south to north above earth-shadow, *except just south of due west*, whence rose a broad dark vertical bar. Faint cirri to south now lit up. 5.28, bars to north and south still visible, and no glow above earth-shadow at anti-solar point. Glow lasting at 5.30. Cirri in east quite dark again, but the cirri near Venus and to south white. Former now in vertical lines, but upper edges blown in wisps towards north. 5.40, stratus low in east by south. A greenish cast given to Venus and Jupiter when the glow strongest. Rosy glow at times noticed during the day. Sun rose about 5.50.

Sun set before 6.20.—6.35, ruddy tinge along east horizon, keeping above earth-shadow as it ascends. 6.45½, cirro-stratus 5° to 10° above horizon, due west again lit up bright (first at 6.30) for two or three minutes, quickly followed by rosy glow in clear sky, [illegible]ree central bands, divided by narrow dark bars,

and corresponding to the single mass on the 11th. 6.53, seven bands to south, a fine trio at an angle of 45°, five to north, much less distinct. No sign now of counter-glow. 6.55, orange next horizon; bars to south as bright as the vertical mass. 6.58, all fading; at no time reached beyond 25° altitude. 7.1, only the bases left of five bars to south, three vertical, and three to north. Positions show well the place of the sun below the horizon. 7.3, rose tints quite gone; none of last night's purple at all. 7.6, the cirro-stratus again tinged at edges. 7.9, as orange fades, last vestige of bars goes; stratus forming; the cirro-stratus still lit up. Sky very clear for York; none of the hazy clouds which accompanied the glows last season. 7.15, still red tinge along horizon.

September 14, *morning*, 5.7.—Find sky bright on waking; rose above, orange to greenish, yellow below; orange most marked, but rose wider spread, involving Venus, which, with Jupiter and moon, showed complementary effect. Only one dark bar, low down to north. Coloured area increased up to 5.15; fairly bright at 5.20; perceptible at 5.25. *Counter-glow* very marked at 5.20, massed above earth-shadow at anti-solar point, just where, yesterday, there was no ruddy tinge. *No* cirri about, only light scud low down to east, from north to south. Very clear.

This evening (14th) scud covered the sky a little before 7, and, so far as I know, nothing special was observable. Is it possible that the bars were due to shadows thrown by cirri below the horizon? J. EDMUND CLARK

Bootham, York, September 14

THE following observations of the warm, yellow circle about the sun, unusual colours of sky and cloud, &c., may interest some of your readers just now. The beautiful, warm, yellow solar halo, silvery white within, was seen on the following dates, usually a little before, during, or after sunset:—May 18, 19, 24; June 11, 25, 26, 27; August 14, 19, 24, 27, 29; September 1, 3, 4, 5. On two occasions, in cloudless sky, the halo was visible from noon to sunset. Unusual and beautiful colours were seen near the sun on August 24, at 3 p.m., September 1, 3, and 5. These colours were first noticed at 2 p.m., November 26, 1883. The extraordinary sunsets began here in November 1883; the dates are as follows:—

1883.—November 6, 14, 25, 28; December 1, 3, 4, 5, 11, 15, 16, 17, 18, 19, 22.

1884.—January 5, 11, 15; February 15, 24.

The colours at sunrise were very fine on November 4, 29, and December 4, 9, 19, 1883; January 12 and February 9, 1884.

J. GLEDHILL

Mr. Edward Crossley's Observatory, Bermerside, Halifax, September 10

EVEN last evening the glow was very marked. At 5.6 a belt of orange-colour lay on the horizon near the point of sunset, having a breadth of 4°. From this base shot up the bluish-white cone, while on each side (south-west and north-west and skirting the horizon) the sky had a smoky-brown aspect. The whole was overtopped by an arch of a pale smoky-pink hue, the outer circumference of which reached an altitude of about 30° as measured from the horizon. At 5.8 the bluish-white cone had become more intense, and the eastern sky was of a pale green. At 5.12 the bluish-white cone, with brown sides and orange base, was very distinct. At 5.14 I noted a long ellipse of intensely blue sky, the meridian forming its major diameter. On each side, west and east, were areas of bluish-white, the latter apparently being a reflection of the former, and having a base on the eastern horizon of dull greenish-brown. At 5.21 I examined the sunset sky with the spectroscope. The low sun-band was becoming dark; the merest possible vapour shading appeared, detached, to the left of D, the little "*c*" lines were clear, and B (dry gas) intense. At 5.31 the low sun-band had become much deeper. By 5.38 a secondary glow had appeared: pale lemon extended for some 7°, overtopped for the next 20° by an intense smoky-pink, the opposite sky being a dull green, while that immediately above the horizon south-west and north was brown, and the landscape was tinted with a warm glow. The little "*a*" band was now intense, so also was the low sun-band, and all trace of vapour effects to the left of D had vanished. At 5.43 the glow was "settling down" and had a total extension of some 14°, 7° of orange and 7° of green. The whole thing finished off with a belt of pale sea-green about 10° in diameter shortly after 6 o'clock.

I have taken a great number of observations *in re* since my arrival in Australia last December, and am now collating them in accordance with the request of the Editor of NATURE (vol. xxix. p. 157). In a word, I am at present strongly in favour of the volcanic hypothesis, and claim to have sufficiently shown in a paper recently delivered before the Royal Society of South Australia that the relatively high pressure prevailing *over* the low pressure of Southern Asia at the time of the eruption prevented the dust from reaching India, so as to produce the effects of the "glow," until the lapse of a fortnight, and that the dust travelled westwards and southwards aided by the rapid equatorial rotation of the earth and the vertical distribution of pressure in oceanic regions south of the Line.

CLEMENT L. WRAGGE

Torrens Observatory, near Adelaide, July 31

P.S.—I have repeatedly observed the "glow" in broad daylight, and it is now (*noon*) visible as a bluish-white glare.—C. L. W.

LAST year, when staying at this place, I was much struck by the clearness of the air, the deep blue of the sky, and steadiness of the stars. Moreover I used to notice on every clear day that the highest cirri, when near the sun, exhibited very beautiful spectrum colours. They did not behave as I have seen them behave once or twice in England, viz. take up all the colours in regular succession as their angular distance from the sun altered; but each cloud exhibited the colours in an apparently irregular manner that reminded one of the appearance of mother-of-pearl. This year it seems to me that the air is of a less deep blue, and on every clear day there has been a very marked reddish glow all round the sun. This red glow in the midst of what would otherwise be a pure blue sky has been very noticeable. It has nearly, though not quite, "swamped" the diffraction colours spoken of as so remarkable last year. W. LARDEN

Avolla, Sion, Canton Valais, Switzerland (about 6500 feet)

Pipe-Clay

I WAS forcibly struck the other day by the analogy between the beds of plastic clay (called here pipe-clay) which are everywhere met with interstratified with the different drifts of wash-dirt, river-sand, &c., in the tin-mines about this country, and what was then to be seen in our own mine here. The mine had been under water for about a month. On pumping the water out, we discovered a layer of particularly fine, soft mud, four inches in depth, of about the consistency of cream. It is evident that any animal or vegetable substance dropping into this layer would sink through it and rest on the bottom. The pipe-clay contains no fossils except portions of trees which rest on the bed beneath it. Now, from the evidence before me here, I am led to the conclusion that the beds of pipe-clay were formed under like circumstances as these. The old torrents which brought the drift down from the mountains were undoubtedly continually changing their paths as they traversed the valleys, being dammed by accumulations of timber and boulders, thus causing the diversified and mixed-up appearance of the beds, some of them containing huge trees and heavy stones: these are the beds which contain the richest deposits of tin ores, others being beds of fine quartz sand, with beds of materials graduated between the two descriptions, and the beds of pipe-clay interspersed. These last vary considerably in depth. I have seen them all thicknesses between one inch and twenty feet.

The beds containing heavy materials were undoubtedly brought down by tremendous torrents caused by heavy rainfalls; the lighter materials by the shrunken torrents during dry seasons, or from a diversion of the course of the main stream. If this is the case—and it seems to me most probable—I think that it is a fair deduction to say that the pipe-clay was deposited in ponds left by the decreasing torrents in their periodically-used channels, which ponds would probably be perfectly still water, and favourable for such a deposit, in the same way as this mine was in a position favourable for the deposit of four inches of slimy mud in a month. I am at a loss to account for the fact that these beds (of finer materials) do not contain any animal remains. The heavy beds contain very much heavy timber, but of course all smaller and more delicate animal or vegetable remains would be smashed up here: this does not, however, apply to the other beds, if my theory is correct, and yet no

fossils are to be found here, nor can I hear of any having been found elsewhere.

With reference to the suggestion of the Rev. J. E. Tenison-Woods (NATURE, May 22, p. 76), that the tin is probably derived from below the gneissose formation and above the granite, this seems to me a most probable conclusion, although I have seen no more of the clay-slate than water-worn blocks mixed with the blocks of quartzose granite in this mine; but I do not feel quite certain that the so called laterite is derived from this clay-slate formation, as it contains very much quartz sand, and, so far as I have seen here, nothing that resembles a sand resultant from the decomposition of the clay-slate.

I was over in Kintah the other day, and heard of a hot spring at a village called Samban, near Ipoh; there are, I believe, several others about in the peninsula, and I understand that sulphuric acid is emitted from the bottom of some of the mines at Lahot, especially M. De la Croix'. These are the only signs of volcanic action since the granite that I have heard of or seen.

In conclusion I cannot help indorsing the Rev Tenison-Woods' opinion that there are great quantities of tin here only waiting to be worked. A. HALE

Ulu Bakow, Perak River, July 25

Repulsion

SIR W. THOMSON, in his address at Montreal, asks: "May it not be that there is no such thing as repulsion, and that it is solely by inertia that what seems to be repulsion is produced?" And he proceeds to illustrate this by the case of two mutually attracting bodies approaching, then dashing past one another in sharply concave curves round their common centre of gravity, and so flying asunder again. He adds that this idea was suggested to him thirty-five years ago by an observation of Sir H. Davy. And I think one may gather that his impression is that it is one that has not presented itself to other minds in the interval.

I cannot but think that such an idea must have been "in the air," among mathematicians, from the time when first any similarity was thought of between the action of molecules and masses. At any rate, I certainly never read Davy at first hand, and yet, in 1874, I published an "Elementary Exposition of the Doctrine of Energy," intended for schools (which I fear fell dead from the press), and in a section on "Molecular Theories" I wrote as follows:—

"Two bodies subject only to their mutual attraction, if their motions at any one moment are not in the same straight line will never come in contact. . . . The orbit may be like a comet's, very nearly a straight line in the greater part of it, turning sharp round at each extremity, . . . at the nearest with enormous impetus. This shows that what we call elasticity in a mass *may*, wholly or in part [this was meant to exclude the case of *direct* collision, as to which Sir W. Thomson also enters a *caveat*], be the result of *attractive* force combined with motion. A blow given on the surface of the solid mass drives the particles inwards; but the result may be a pirouette round some of their inner neighbours, and an equally strong outward impetus driving back the hammer with an energy proportionate to that which it had given."

My intention in that section was to excite thought in school teachers and apprehensive and energetic scholars; but I did not imagine I was starting a novelty. He who propounds a working hypothesis of molecular action in which this idea plays a part will have the whole credit. D. D. HEATH

Kitlands, Dorking

Fellow-Feeling in House-Flies and Swallows

THE moral feelings of animals being as interesting as their intelligence, perhaps the readers of NATURE would care to hear of a curious instance that I just now witnessed of fellow-feeling in the common house-fly. A number of them had collected in the top of a window, and I was about to open it to let them out, when I saw a wasp seize one, as I have seen many seized this year, but never before, though I have often seen them feed greedily on maimed *bees*. The wasp was about to sever the head from the body of his victim, when a fly—by no means a large one—flung itself violently against the captured one, trying apparently to knock it away from the wasp; it did not attack the wasp. This was done again and again, whether by the same fly or another I could not tell, the action was so rapid; at last the body of the fly was knocked away, but the wasp retained the head and devoured it. It then grasped another, and again a fly dashed at it, and another, and another, though they were all evidently afraid of the wasp; and no wonder; it seemed very fierce and hungry. The action of the flies was quite unmistakable. I called another person to watch it with me, and she was as much surprised as I was, and inclined to kill the wasp; but I thought we could spare a few flies, notwithstanding this unexpected discovery of fine feeling in them, and I would not let her disturb the balance of Nature.

I was once a delighted witness of a still more curious instance of fellow-feeling in some young swallows. Six of them were sitting on a low roof, and were being fed by the old bird, who flew by from time to time, and put something into one or two of the open beaks. Each time, as soon as they saw the parent coming, which was some time before I did, they all stood up, whirring their wings and chattering; all, that is, except the last but one, and that seemed to be weak and unable to rise, and so got nothing. At last the two that flanked it, after a great deal of chattering over it, managed to raise it up by putting their beaks under its little white bosom; and then and there the dear little brotherly things wedged it up between them with the prettiest air of compassion and patronage, so that it had a fair chance with the others. And it seemed quite a chance which was fed, yet all sat down apparently perfectly contented and good-humoured afterwards. It was a pretty sight, and I was grieved when, some boys coming by, they took to flight.

Sidmouth, September 13 J. M. H.

Rainbow on Spray

THE appearance noticed by "G. H." in last week's NATURE (p. 464) is a well-known sight at sea under certain conditions. I first saw it from the deck of the Anchor Line s.s. *Bolivia*, about two hundred miles east of Cape Cod. It lasted for half an hour between 10 and 11 a.m. The sea was going down after heavy weather: the sun was shining brightly in a clear blue sky, with light, fleecy clouds scudding along. A fresh westerly breeze cut the tops off the rollers and cast the spray high in the air. When the procession of waves passed through an area more or less opposite to the sun, their crests took up beautiful rainbows; there were thousands of them, and as the steamer rolled and pitched, the changing angle caused the spray on some waves to take more of one or other primary colour, seeming now blue, now red, and again yellow golden.

Leeds, September 13 FRANK E. CANE

JAPANESE EDUCATION

THE Japanese Government, having decided to take a more prominent part in the Health Exhibition than they did last year in the Fisheries—due, we believe, in the latter instance to the fact that they had a Fisheries Exhibition of their own in Tokio at the same time—have appointed a Commission to superintend the Japanese Section, among the members of which is Mr. S. Tegima, the Curator of the Tokio Educational Museum, who has been specially appointed to superintend the Educational Section. To accompany the exhibits in this Section the Government have published a little hand-book, which has been reproduced in the *China Telegraph*, and which contains the most exhaustive account of modern Japanese education, its system, and results, that we have seen in any European language. The Annual Report of the Minister of Education is little more than a mass of statistics; the number of children attending primary, secondary, &c., schools for some years past is carefully given, but we are left to guess at the subjects taught and the course of instruction in these establishments. We are not grumbling at the Report on this ground; it is what it professes to be; we merely desire to point out the special interest of the present little work. The Japanese can look back with pride on a large—a very large—portion of the national work of the past fifteen years; and in education, whatever it may have been in other departments, there has never been the slightest faltering or doubt as to the wisdom of extending the benefits of an improved system to every village and hamlet in the Em-

pire. And perhaps the statesmen who have steadily pursued their policy in this respect when the cry for economy, even at the expense of efficiency, was rising round them, have their reward even now. A Minister of State who recently visited Europe, talking to an English friend of the future of his country, stated that in Japan they trusted to their system of popular education acting on the intelligence of their people to prevent the spread of revolutionary doctrines; the schoolmaster was abroad in the land, and its rulers could rest safe from that danger at least.

The Education Department in Japan is one of the ten principal offices of State, its head ranking as a first-class Minister. It has the usual staff of Vice-Ministers and Secretaries, who carry on the business, and from time to time visit and inspect the various districts. All the local governors are, in educational matters, directly under the control of the Minister. The salaries of professors range from about 1000*l.* per annum (foreigners probably) to 250*l.*, and those of teachers from 100*l.* to 30*l.* The latter are, we believe, considerably higher in proportion than those of Board-school teachers in this country. School text-books are chosen with great care, and by the Department itself; indeed almost all the books are compiled and published by the Government. In the capital two establishments have been organised in the interest of education—one a library where works in all languages are collected, and placed, under certain slight restrictions, at the disposal of the public; the other the educational museum, in which objects necessary to general education are collected for the benefit of those engaged in it. The rules by which all schools are governed, whether they are local, general, or private, appear ultimately to come under the notice of the Minister of Education for his approval, so that the administration is a highly centralised one. An important feature of the work is the number of students sent abroad by one or other of the Departments of State. The Education Department has sent fifty in the past seven years, and there are at present twenty-two abroad, of whom seventeen are in Germany, one in Austria, two in England, one in France, and one in America. All these are graduates of the Tokio University, who were specially selected by the Minister of Education for the purpose of being sent abroad. The great preponderance of these in Germany is remarkable, and would appear to show that the Japanese are inclined to discard English and American educational institutions (which have had their day in Japanese estimation) for those of Germany. On the other hand, it may be that those are mostly medical students, who have from the beginning been sent to German Universities. Before coming to the various classes of schools, the statistics had perhaps better be given. The following are for 1882, the details for 1883 not being yet forthcoming:—

	Number	Professors and Teachers	Pupils
Elementary schools	28,908	76,769	2,616,879
High schools	173	934	12,315
Normal schools	71	602	5,275
Universities	2	135	2,035
Technical schools	98	975	8,829
Other schools	1,026	2,598	72,260

Of the 2,616,879 pupils at the elementary schools, only 733,691 are girls. Nearly the whole of these schools are maintained by the various local Governments, *i.e.* out of local, not Imperial, taxes. The whole system is administered under a code first promulgated in 1872, re-issued in an improved shape in 1879, and again revised in 1881.

The lowest schools of all are the Kindergarten, where children under school age are taught for three years reading, writing, ciphering, embroidery, paper-plaiting, drawing, &c. The next grade is the elementary schools, where a general education is given, and at which attendance is compulsory. The district for such a school varies with the population and resources; but theoretically, and as a rule in practice, one exists in every ward and in every village. The course of these schools is divided into lower, intermediate, and higher grades. The lower grade course comprises the elements of morals, reading, writing, arithmetic, singing, and gymnastics; the intermediate, besides these, includes geography, history, drawing, physics, and natural history; while the higher grade adds chemistry, geometry, physiology, and political economy. Teachers receive certificates either for a certain class of schools or for a special subject from the normal schools, or from the local inspectorates. Committees or Boards, similar apparently to our School-Boards, are formed in each district, but their functions are limited to seeing to the attendance of the children, and they seem to have no power over the finances of the school. The next grade of schools is the "middle schools," organised in each district according to the local conditions and demands. Their object is to give higher instruction in the ordinary branches of study, so as to prepare students for liberal pursuits or for the more advanced schools. In addition to the subjects already specified, we find the middle-school course including elementary mathematics, natural science, geology, Japanese law, and one European language. To provide a model for these schools, the Minister of Education established a middle school at Osaka, to which reference can be made. There is only one University, that of Tokio, with four departments, law, science, literature, and medicine. Nothing need be said of this, as it is organised in the usual way. There are two preparatory schools for it, and the department of science appears to be well equipped with astronomical and meteorological observatories, botanical gardens, and museums.

In addition to these, which may be called the ordinary educational institutions, there are special colleges attached, or under the control of certain Departments. Such are the Military Academy, the Engineering College, the Training Schools for the Navy and Army, the School of Marine Engineering, of Forestry, Law, Telegraphy, &c. The normal schools for the training of teachers should also be noticed. They are established in almost every district, and now number seventy-six. The Government has provided two model normal schools in Tokio, one for male teachers, the other for females, and it is worth noticing that the latter was opened by the Empress herself. There are two schools of agriculture, one near Tokio, the other at Sapporo in Yezo. In the former the students are instructed in the science of agriculture, in veterinary science and agricultural chemistry, while in the latter stock-rearing and cultivation are taught.

These appear to be the chief features of the Report, and it is much to be wished that the compilers had given some information regarding the part played by Europeans in Japanese education. A comparative statement of the number of Europeans employed in the Department or in local schools eight or ten years ago, and now how far the posts they occupied have been abolished, or occupied by Japanese found suitable for the work, would have been interesting.

BRITISH BIRDS AT THE NATURAL HISTORY MUSEUM

VISITORS to the new Natural History Museum can scarcely have failed to notice the many improvements which have been made in the re-arrangement of the zoological collections since their removal from Bloomsbury to South Kensington. Not only is there greater space now available for exhibiting the contents of each gallery, but a large proportion of new specimens have been introduced into the cases.

It is of course not to be expected that stuffed animals, however well preserved, will last for ever, and some of the

specimens in the national collection are considerably more than a hundred years old. A certain amount of "weeding out" from time to time is consequently unavoidable, and is by no means so easy a process as might be supposed. The preservation of "types," that is, of the original specimens from which the species were first described, has very properly been considered of great importance; they have been withdrawn from exhibition and exposure to light, and relegated to the study series; but old and badly-mounted specimens of no historical value have been discarded, and their places filled with recently-obtained fresh examples of the same species, preserved and mounted with all the skill which modern taxidermists have been able to bestow upon them.

The Osteological, Cetacean, and Coral Galleries contain collections which were but incompletely represented in the exhibition rooms of the old building, and in fact, offer to the visitor entirely new exhibitions, of which those who have been engaged in their formation and arrangement may well be proud. None of these, however, appeal by their direct instructiveness to the British public, or are appreciated by them so much as the series of groups of British birds illustrating their mode of nidification, which is placed on the right and left of the central hall.

Here the visitor finds a collection of British birds, in which each species is separately represented by a pair of old birds in the plumage peculiar to the breeding season, with its nest and eggs, not merely in a natural position, but in the actual position in which they were found; the arboreal birds being placed on the identical branches which they themselves selected for nidification, the ground breeders remaining on the actual patch of ground, whether grass-grown or heather-clad, in which they had designed to rear their young.

It is needless to enlarge upon the advantage to be derived from a lesson thus accurately imparted, or upon the excellent opportunity thus afforded for comparing the variation in structure of nests built by birds belonging to different orders and families. As an aid, also, to the identification of the owner of a nest unknown to the finder, the series is a useful one, and will become more so as the collection is extended, for the process of forming and preparing such a collection must be slow. It is nearly four years ago since Dr. Günther commenced its formation, and without the aid of ardent lovers of nature like Lord Lovat, Mr. T. Harcourt Powell, Mr. D. Parker, Colonel Irby, and especially Lord Walsingham, it would have been impossible for him to have made this series, as it is, one of the most instructive attractions of the Natural History Museum. As for ornithologists, it is difficult to say where the interest ceases.

Not very long since Mr. H. Seebohm gave a lecture at the Zoological Gardens on "Birds' Nests," and could he have pointed to these beautifully-mounted cases at South Kensington, he would have had the most appropriate illustrations possible to his discourse.

From an attentive study of the subject he considered that nests might be roughly grouped into five classes, according as the birds which owned them relied for the safety of their eggs: (1) on the concealed position of the nest; (2) upon the inaccessible position of the nest; (3) upon the protective colour of the eggs; (4) upon the protective colour of the sitting hen; (5) upon their own ability, either singly, in pairs, or in colonies to defend their eggs.

Illustrations of all these five classes (and Mr. Seebohm might have added a sixth, viz. contrivances employed for concealing the eggs on the bird leaving its nest) may be seen in the British Museum cases, and furnish as good a basis as any for studying the series.

Starting from the entrance to the Mammalia Gallery, and proceeding towards the staircase, we at once come upon several cases of birds which rely for the safety of their eggs upon the concealed position of the nest. Here we find a pair of dippers with their nest of green moss most skilfully constructed and domed, placed just under a moss-grown stump overhanging the water. Patches of the same moss around and about the stump deceive the eye and render detection of the nest very difficult, unless the bird is seen to leave or enter it. A section of the nest, represented by an illustration, shows a curious feature in its construction. It is not only cup-shaped and domed, but the front edge of the cup curls over towards the centre of the nest, as if to protect the pure white eggs from any drip or spray from the stream in whose banks the nest is placed.

Close to this group we find two cases of woodpeckers, the green woodpecker or "yaffle" and the greater spotted woodpecker, both of which deposit their white eggs in the hole of a tree, the aperture of which as a rule is only just large enough to admit the bird, and consequently the nest, composed of dry chips and bits of bark, is well concealed. But the woodpeckers might, with almost equal propriety, be placed amongst those birds which rely for the safety of their eggs on the inaccessible position of their nest.

It has been stated that as a general rule all eggs which are deposited in holes or in well-roofed nests are white, and certainly we have illustrations of this in the case of the dipper, woodpecker, owl, kingfisher, swift, sandmartin, and other birds; but, on the other hand, the jackdaw, nuthatch, tree-creeper, and various kinds of titmouse, all breed in holes and yet lay coloured eggs; while the pigeons, doves, grebes, and waterfowl lay white eggs in open nests; so that no precise rule can be laid down on this head.

Almost all the small passerine birds may be said to rely for the safety of their eggs on the concealed position of the nest; hence it is difficult to name any without giving a long list of names. In the Natural History Museum series the following examples may be noted:—The yellowhammer, with its nest of dry grass placed in a clump of dead furze, whereby a contrast of colour is avoided which might lead to the detection of the nest; the meadow pipit, with its nest concealed in meadow grass; the reed bunting, with its nest placed low down, to escape observation, in a clump of rushes. Were this nest placed higher up in a plant of such open growth, it would be sure to attract attention. In like manner the linnet and Dartford warbler in furze, the skylark, yellow wagtail, and whinchat in meadow grass, all furnish illustrations of variety in the art of concealment as practised by the tiny architects.

Amongst birds which rely for safety on the inaccessible position of their nest may be mentioned the hawks and owls, raven, chough, kingfisher, sandmartin, moorhen, coot, and grebe. There are few eggs more difficult to take than those of the peregrine falcon, raven, and chough, from the habit of these birds to nest in precipitous cliffs; the kingfisher and sandmartin, breeding in holes which sometimes extend several feet into a bank, and often not in a direct line, evidently imagine themselves safe from molestation; while moorhens, coots, and grebes, making slovenly-constructed nests upon soft, treacherous ground, or amongst sedges, flags, and other water plants which are unapproachable without the aid of a boat, afford another instance of how the same object may be achieved by a different method. One cannot fail to note that the more slovenly the nest of these water-birds the more likely is it to escape detection, for, were it well shaped and neat in appearance, its very neatness amidst a mass of wind-strewn rushes or tangled growth of water-weeds would be sure to attract attention towards it.

To give instances of birds which rely for safety on the protective colour of their eggs, we might mention the nightjar, peewit, stonecurlew, snipe, woodcock, ringed

plover, oystercatcher, the various species of tern or sea-swallow, and, generally speaking, all those birds which habitually deposit their eggs upon the ground, with little or no vestige of a nest.

Only those who have sought for and found the eggs of the peewit, stonecurlew, ringed plover, and oyster-catcher can have any true idea of the remarkable approximation in the colour of the eggs to the ground whereon they are laid, the two first-named resembling the small clods and stones upon the fallows where they are found, the two last-named counterfeiting the freckled, water-worn pebbles of the beach.

Many of the above-named species and others are already represented in the Museum series. The group of the ring plover with the newly-hatched young hiding between, and scarcely distinguishable from the pebbles, is charming by its simplicity; whilst the bit of Scotch moor with the woodcock's nest will arrest the attention of every sportsman whose personal experience of this bird has been limited to a glimpse of it in the shooting season.

If we look around the collection for instances of species which rely for the safety of their eggs on the protective colour of the sitting hen, we shall find excellent illustrations in the case of the pheasant and grouse, two of the most life-like groups in the series. In the former

Grebes and Nest

case we seem to have a little bit carved out, as it were, and carried away from an English wood in spring-time—primroses, bluebells, and all!

It is probable that in this same class we must include all the game birds, a large number of the passerine birds (excepting those in which, as in the tits, wagtails, pipits, larks, and some of the warblers, the sexes are alike in plumage), the woodcocks, snipe, and ducks. But of these, as will appear from our previous remarks, the passerine birds would as well rely for safety on the concealed position of the nest, and the woodcock and snipe, on the protective colour of their eggs.

In a notable essay entitled "A Theory of Birds' Nests," published some years ago, Mr. A. R. Wallace, amongst other ingenious propositions, attempted to establish the rule that, in all cases where the hen bird is brightly coloured like the male (as in the kingfishers, woodpeckers, tits, &c.) nidification takes place either in a hole or in a roofed nest; while in cases where the sexes differ in plumage, and the hen bird is of a dull colour (as in the pheasants, for example), the nest is open and the sitting bird exposed to view.

This theory, though at first sight plausible, is really untenable; for the exceptions which may be brought forward in both classes are as numerous as the cases cited in support of it. On reflection it is apparent that jays, orioles, and pigeons (many tropical species of which are brilliantly coloured), according to Mr. Wallace, ought to

be found breeding in holes or in roofed nests, their eggs concealed from view; but, on the contrary, they build open nests, some of them, as with the pigeons, being very clumsy and conspicuous structures. On the other hand, birds like the creeper, nuthatch, wren, willow wren, and chiffchaff, with the hen birds of sombre colours, would be expected, on Mr. Wallace's theory, to build open cup-shaped nests wherein the sitting bird would be exposed to view; but the two first-named breed in holes of trees, and the others all construct domed nests. It would be easy to take exception to other propositions made by Mr. Wallace, and generally to combat his ingenious theory; but such is not our object here. We have referred to his essay rather for the purpose of redirecting attention to it in connection with the admirable series of birds' nests in the collection under notice which furnishes the reader with illustrations to many of Mr. Wallace's remarks.

As to the birds which rely for the safety of their eggs on their own ability to defend them, whether singly or in pairs or colonies, familar examples occur to us in the partridge, peewit, and black-headed gull. There must be few observant naturalists who have walked abroad in the nesting time and have not witnessed and admired the extraordinary efforts made by some or all of these birds to decoy the intruder away from their eggs or young by feigning lameness, or to frighten him away from the spot by boldly dashing at his head with loud reiterated cries.

The group, of which an engraving is here given from a careful sketch by Mr. Charles Whymper, represents a pair of little grebes, or dabchicks as they are provincially called, at a pond-side, with their characteristic nest of weeds. The hen bird is just leaving the nest to join her mate, having hastily covered her white eggs to conceal them.

The taxidermist, it will be observed, in this case has been obliged to show them partially uncovered, in order to explain what otherwise might remain unsuspected by those who are unfamiliar with the habits of these interesting birds.

NOTES

THE Queen has been pleased to confer the dignity of a Knight of the United Kingdom on John William Dawson, LL.D., C.M.G., Principal and Vice-Chancellor of the McGill University, Montreal, in the Dominion of Canada.

THE death is announced of Dr. J. J. Woodward, surgeon, United States Army, the well-known microscopist, whose admirable photo-micrographs, produced during his official connection with the Army Medical Museum, Washington, have given the pre-eminence to America for this branch of scientific microscopy.

THE Electrical Conference at Philadelphia has adopted resolutions that steps should be taken to legalise in America the ohm adopted by the Paris Conference, as also the ampere and volt, as electrical standards of measure. It was proposed by Mr. W. H. Preece that the Committee should consider the adoption of the English watt as a unit of power; this was also adopted.

PROF. ROBERT S. BALL lectured in Philadelphia on Wednesday night last week on the distances of the stars. He had a large audience at the Academy of Music.

THE first aërial voyage in England having taken place from the Honourable Artillery Company's ground at Finsbury on September 15, 1784, in the presence of the Prince of Wales, afterwards George IV., preparations were made to fittingly celebrate the 100th anniversary of the event, which occurred on Monday. A committee successfully perfected the arrangements for the ascent of three huge balloons from the grounds at the rear of the Finsbury Armoury, [illegible] after 2 in the afternoon, just a century before, Lunardi, the secretary to the Neapolitan Ambassador in London, started upon the first aërial voyage performed in this country, and ultimately descended, at 20 minutes past 4, in safety in a meadow at Standon, near Ware, Hertfordshire. In the Long Room, Col. Beaumont, R.E., presiding, M. W. de Fonvielle, editor of *La Lumière Électrique*, delivered an address, in which he described the improvements made in the construction and the gear of balloons during the past century, particularly alluding to the improvements effected by the late Mr. Green, the inventor of the cone anchor, which had been the means of saving the lives of so many aëronauts when they drifted out to sea, and had been rescued by passing vessels. He spoke hopefully and sanguinely of the ultimate success of the efforts now being made by gallant French officers to steer balloons by the medium of electric currents.

A SECOND ascent was made on Friday at Meudon in Capt. Renard's new balloon, but this time without the success which attended the former experiment. There was a good breeze. On the previous occasion, it will be remembered, there was only a slight breeze. After resisting the wind and remaining stationary, or nearly so, for a few minutes, the balloon was carried in the direction of Versailles, and, on one of the batteries ceasing to work, descended near Versailles. From there the balloon had to be dragged back to Meudon. The inventors assert that, but for the accident to the battery, they would have returned to Meudon in the teeth of the wind.

M. REGNARD has made a series of experiments on living organisms under high pressures. Yeast was found to be latent after having been subjected to a pressure of 1000 atmospheres for one hour; an hour later it began to ferment in sweetened water. Starch was transformed to sugar by saliva at 1000 atmospheres. At 600 atmospheres Algæ were able to decompose carbonic acid in sunlight, but they died and began to putrefy after four days. Cress-seed after ten minutes' exposure to 1000 atmospheres were swollen with water, and after a week began to sprout. At 600 atmospheres Infusoria and mollusks, &c., were rendered morbid and latent, but when removed returned to their natural state. Fishes without bladders can stand 100 atmospheres, at 200 they seem asleep, at 300 they die, and at 400 they die and remain rigid even whilst putrefying.

WE observe that among the three recipients of the gold medals awarded by the University of Christiania is Prof. G. A. Guldberg.

A NEW enemy to the beetroot plantations has appeared in Scania (Sweden) in the shape of the spinach-fly (*Anthomyza spinaciæ*). It has previously been known as an enemy to spinach, but this year it has also attacked the beetroot plants. Dr. Holmgren believes that its appearance is only periodical.

ALTHOUGH a great deal has been done in Norway and Switzerland to examine and measure the glaciers in those countries, comparatively little has been done in Sweden in this respect. During the last couple of years, however, a glacialist, Dr. F. Svenonius, has been engaged in studying and measuring some of the glaciers in Norrland, and we now learn from the report of this gentleman that there are about a hundred glaciers in Sweden, but that they are very small, the whole covering altogether only nine square miles (Swedish). The area had previously been estimated at thirty square miles.

THE Corporation of Southampton have unanimously resolved to support the movement commenced by the Council of the Hartley Institution a short time ago, in favour of a revised Geological Survey of Hampshire and the Isle of Wight on the maps of the 6-inch scale. The Southampton Town Council will

IT is stated that Mr. Gamel of Copenhagen has offered to send his steamship the *Dijmphna* on a second expedition to the Arctic regions *viâ* Franz Josef Land, subject to the condition that the Danish Government will, as a moral acknowledgment of their interest in the Expedition, grant a certain sum of money, however small, towards the Expedition, under Lieut. Hovgaard of the Royal Danish Navy.

THE present number of the *Proceedings* of the Natural History Society of Newport (R.I.) contains several papers on the geology of Rhode Island, and one on its birds. There are, in addition, papers on Mount Tacoma in Washington Territory, by Mr. Bailey Willis; on the migration of birds, by Mr. Taylor; and an account of a journey in North-Western Wyoming, by Mr. Wilson. Several of these papers are accompanied by maps or other illustrations; but unfortunately in most cases only abstracts of the papers are given, while in others we get only the titles.

"CONTRIBUTIONS to the Descriptive and Systematic Coleopterology of North America," Part i., is the title of a paper of 60 pages with one plate of details, by Thos. L. Casey, Lieutenant of Engineers, U.S.A. In it are described about sixty new species and some new genera. Lieut. Casey is, we think, a *débutant* in North American systematic entomology, which sustained so severe a loss lately in the death of LeConte; his descriptions appear to be carefully and minutely drawn up, and from his few introductory remarks he seems to be animated by the true scientific spirit, for he says of them: "If they even serve to identify the species, they may be considered to have done their duty."

IT is known that Clymenias, so widely spread in the Devonian deposits of Western Europe, have not yet been found in Russia—with the exception, perhaps, of the *Clymenia undulata* in the hills of Kielce in Poland. Now, Prof. Karpinsky has discovered remains of this Cephalopod on the Asiatic slope of the Ural, near Verkne-uralsk (*Izvestia* of the Russian Geological Committee, 1884, No. 4). The Uralian fossil is very much like *Clymenia annulata*, Münster, and the few differences render it more like *Clymenia nodosa*, Münster, which is considered by Keyser and Gümbel merely as a variety of the foregoing. Another Clymenia, also found in the same locality, but in a worse state of preservation, seems to belong to *C. striata*. This discovery, while establishing one more feature in common for the Russian and West European Devonian, at the same time widens very much the area of distribution of the Clymenias, formerly so strictly limited to Western Europe.

A NOTE on a possible source of error in photographing blood corpuscles, by Mr. G. St. Clair, F.G.S., communicated to the Birmingham Philosophical Society, is a fruitless attempt to explain as an optical illusion Dr. Norris's asserted discovery by the aid of photography of a third kind of corpuscle in mammalian blood. The author invokes the principle of the formation of images by the passage of light through small apertures, and conceives that Dr. Norris's "colourless disks" are merely images of the end of the microscope tube or the aperture of the eyepiece, and he seems to have taken some pains to obtain such images by placing under the microscope a slide thickly strewn with small steel disks, and receiving the light on a screen beyond the eyepiece. Had he attempted to focus these ghosts and the real images of the disks *at the same time*, or considered a little more closely the elementary optical principles involved, we venture to say the note would never have been written.

qualities assigned to each year, month, and day, each of which is represented by one of twelve letters of the syllabary, seem to have some resemblance to the characters of the corresponding calendar animals—tiger, hare, dragon, serpent, &c. From the five syllabary letters corresponding to the year and month of conception, and the year, month, and day of birth, the chief points of a person's character are made out—the most important determining factors being the year of birth and month of conception. Then come to be considered the effect of the stars which are supposed to rule the years, months, and days. For each year there are nine stars, which have their special qualities; and each man's life is to be ruled by one of them. From the mutual relation of these stars, the life relations of two given people can be made out. One very important application of the system amongst the Japanese is the comparison of the ruling stars of two who are contemplating marriage. Similarly, as each instant of time is ruled by a star, it can be determined whether a given year, month, or day will be lucky or unlucky to a certain individual. The method of divination thus described was illustrated by examples, the author having worked out the horoscopes of Cromwell, Carlyle, Bismarck, Napoleon, and other historical characters. From the discussion which followed, it appears that this elaborate system can be traced back to the earliest period of recorded time in China. It is the so-called system of philosophy embodied in the "Yiking," the oldest of all Chinese books, and if it should turn out, as is contended by some eminent Chinese scholars, that this work is not Chinese in its origin, but Accadian, then Japanese divination would be a Western product.

THE *Japan Gazette* reviews a publication by the native Professor of Botany in the University of Tokio, entitled "Nomenclature of Japanese Plants in Latin, Japanese, and Chinese." The list, it appears, does not include all the plants indigenous to Japan, while it includes many which are in no sense Japanese. It is inferior to Franchet and Savatier's "Enumeratio Plantarum Japonicarum," for while the latter gives more than 2700 distinct species of indigenous flowering plants and ferns, the consecutive numbering in the native work only runs up to 2406, and this includes, besides many foreign plants, numerous mere varieties of species, to each of which a separate number has been appropriated. The author, Mr. Matsumura, is said to contemplate the publication of a more elaborate work.

THE additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Semnopithecus leucoprymnus*) from Ceylon, two Laughing Kingfishers (*Dacelo gigantea*) from Australia, presented by Mr. D. Palgrave Turner; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mrs. E. A. Alldridge; a Cape Hunting Dog (*Lycaon pictus*) from the South-West Coast of Africa, presented by Capt. J. Grant Elliott; a Tigrine Cat (*Felis tigrina*), two Ring-tailed Coatis (*Nasua rufa*) from Brazil, presented by Mr. James Meldrum; a Herring Gull (*Larus argentatus*), British, presented by Miss J. Dunford; a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, presented by Mrs. Frank Wilson; three Violaceus Night Herons (*Nycticorax violaceus*) from South America, presented by Mr. A. Boon; two Yellow-winged Sugar Birds (*Cœreba cyanea* ♂ ♂) from Brazil, presented by Mr. P. A. Fraser; a Tuberculated Iguana (*Iguana tuberculata*) from Brazil, presented by Mr. J. H. Leech; a Brown Capuchin (*Cebus fatuellus*), a Weeper Capuchin (*Cebus capucinus*) from Brazil, a Malbrouck Monkey (*Cercopithecus*

cynosurus) from West Africa, two Victoria Crowned Pigeons (*Goura victoriæ*) from the Island of Jobie, deposited; three Ruddy Flamingoes (*Phœnicopterus ruber*) from North America, purchased; two Ring-tailed Lemurs (*Lemur catta*), a Great Kangaroo (*Macropus giganteus* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN

ASTRONOMICAL PHOTOGRAPHY.—M. Mouchez, the Director of the Observatory of Paris, has communicated to the Academy of Sciences a brief account of some experimental attempts to photograph very small stars, which have been lately made at that establishment. The ecliptical star-charts, commenced by Chacornac, but interrupted in their formation by his decease, were taken up by MM. Paul and Prosper Henry in 1872. These charts include all stars to the thirteenth magnitude; thirty-six of the entire number of seventy-two required for the whole ecliptical zone were completed by Chacornac; these contain 60,000 stars; while sixteen more, containing 36,000 stars, have been constructed by MM. Henry, who will shortly finish four others, with 15,000 stars. But they now find themselves in face of a difficulty which can hardly be overcome by the ordinary process of charting. The condensation of stars in those regions where the Galaxy traverses the ecliptic is so great as apparently to defy an accurate and complete representation of their stellar contents, on the methods adopted for the greater part of the zone, notwithstanding all the experience and well-known skill of the observers.

They have accordingly had recourse to photography, and their first attempts with a provisional apparatus have succeeded so well that there is every reason to expect by this means a solution of the difficulty in question. On plates covering an extent of 3° in right ascension and 2° in declination, obtained with an objective of 0·16 m. diameter and 2·10 m. focal distance, achromatised for the chemical rays—which M. Mouchez exhibited to the Academy—there are shown some 1500 stars from the sixth to the twelfth magnitude, *i.e.* to the limit of visibility of an objective of that size; the images of the stars have diameters nearly proportional to their brightness, except in the case of the yellow stars, which come out somewhat fainter. These encouraging results have led MM. Henry to commence the construction of a large objective of 0·34 m. diameter, which will be mounted by M. Gautier, and it is anticipated that with this instrument, in the course of an hour, a chart of the stars, to the twelfth magnitude at least, and probably to the thirteenth or fourteenth, of the same dimensions as one of the published charts, will be obtained; a work which would otherwise require many months of assiduous labour.

THE BRITISH ASSOCIATION CATALOGUE OF STARS.—In a book-list circulated during the last week by a Dresden firm, a copy of this Catalogue has a price of 200 marks (10*l.*) attached, excused by the addition, "Aeusserst selten." As regards star-places the volume is out of date, and the same may be said of the so-called constants for reduction of mean to apparent positions, if any degree of accuracy be required; but it is nevertheless still sought after, especially by those who are commencing the study of astronomy, as will be well known to every one who has any pretence to be considered a practical authority; and it must be admitted that, for purposes of identification and for synonyms in some of the principal older catalogues, the B.A.C. has still its uses. The question arises, whether there would not be a considerable demand for a new general Catalogue of the principal stars, or of stars to the limit of naked-eye vision, brought up from the best authorities to, say, the epoch 1900, but unencumbered with the reduction-quantities, which would materially diminish the expense of formation. A Catalogue of this description, we take it, is not likely to be again provided from the funds of such a body as the British Association, and perhaps the most feasible method of producing it would be by way of subscription. One difficulty would no doubt consist in securing a supervisor of the plan and formation of the work;—perhaps few competent persons could be named who have the leisure which Baily fortunately possessed, and to which we owe not only the B.A.C. but the Catalogues of Lalande and Lacaille.

THE COMET 1884*b*.—Prof. Krueger's telegram to Melbourne led to the observation of this comet, both by Mr. Ellery and Mr. Tebbutt on July 24. Mr. Tebbutt sends us several letters which he has addressed to the *Sydney Morning Herald*.

THE BRITISH ASSOCIATION

REPORTS

Report of the Committee, consisting of Dr. Gladstone, F.R.S. (Secretary), Mr. William Shaen, Mr. Stephen Bourne, Miss Lydia Becker, Sir John Lubbock, Bart., M.P., F.R.S., Dr. H. W. Crosskey, Sir Henry E. Roscoe, F.R.S., Mr. James Heywood, F.R.S., and Prof. N. Story Maskelyne, M.P., F.R.S., for the Purpose of Continuing the Inquiries relating to the Teaching of Science in Elementary Schools.—Since the reappointment of your Committee at Southport no legislation affecting the teaching of science in elementary schools has taken place, and it is yet too early to estimate the whole influence of the Education Code of 1882 in that respect. Some indications, however, have been gathered from the Blue-book and from some of the large Boards. The first effect of the change of Code upon the teaching of science is shown in the return of the Education Department for this year; but as the tabulated statements only extend to August 31, 1883, they contain merely the results of those examinations that were made of schools which came under the new Code between April 1 and August 1, 1882, or about 28 per cent. of the whole. The following conclusions may be drawn: (1) Elementary science was taken up by scarcely any schools examined during these months, the number of departments that took it up as the second class subject being only 15, while 3988 took up geography, 1644 (girls) needlework, and 114 history. It must be remembered that geography is more scientific than it was before, but needlework is rapidly displacing it in girls' schools. (2) The exclusion of the Fourth Standard from instruction in specific subjects has reduced the number of scholars so taught by 56·6 per cent.; but the remaining 43·4 per cent., that is to say, the children in Standards V., VI., and VII., do receive a larger proportion of scientific teaching. The actual number of children examined during these four months in the mathematical and scientific specific subjects is given in Column I. of the following table; Column II. gives the estimated number who would have been examined under the old Code; Column III. the number of those who would have been above Standard IV.

Subject	Col. I.	Col. II.	Col. III.
Algebra	8,256	1,847	799
Euclid and Mensuration	604		
Mechanics, Scheme A	635	1,393	603
,, Scheme B	—		
Animal Physiology	7,078	8,537	3,696
Botany	1,020	642	278
Agriculture (principles of)	422	—	—
Chemistry	368		
Sound, Light, and Heat	196		
Magnetism and Electricity	1,133		
Domestic Economy	6,090	16,890	7,232
Totals	25,802	29,309	12,608

Comparing Columns I. and II., it will be seen that the actual number examined in these subjects is not much less than would have been examined under the old Code, when the Fourth Standard was included; but the number of girls who have taken up domestic economy is 10,800 less. If we compare Column I. with Column III., which embraces the same Standards, it appears that double the number of children have passed in these mathematical and scientific subjects. This is, no doubt, mainly due to the fact that English literature and physical geography are removed to the category of class subjects. The great gain has evidently been to the study of algebra, that subject and Euclid being taken up by about eleven times as many as previously took up mathematics. Animal physiology and botany have also largely increased. Mechanics is about the same, while of the new subjects magnetism and electricity has proved itself the favourite, while agriculture, chemistry, and sound, light, and heat follow in order. The only subject that has actually lost ground is domestic economy, which is no longer obligatory in girls' schools if a specific subject is taken. The following table gives the number of passes in specific subjects made by the London School Board children in 1881–82, and in 1883–84. The second column gives the estimated number of those that were made in Standards above IV., corresponding to Column III. in the previous table.

Subject	1881-82 Standard IV. and upwards	1881-82 Over Standard IV.	1883-84
Algebra	213	101	3,113
Euclid and Mensuration			139
Mechanics	48	23	165
Animal Physiology	8,667	4,094	5,657
Botany	534	252	686
Agriculture (principles of)	—	—	299
Chemistry	—	—	198
Sound, Light, and Heat	—	—	179
Magnetism and Electricity	—	—	825
Domestic Economy	9,597	4,533	3,478
Totals	19,059	9,003	14,739

The following information has been furnished from the Manchester School Board :—

I. Class subjects.

Departments	1882 Grammar	1882 Geography	1882 Needlework	1882 History	1883-84 English	1883-84 Geography	1883-84 Needlework
Boys	26	24	—	1	31	30	—
Girls	26	11	8	1	28	4	23
Junior	13	10	—	—	21	13	3
Mixed	4	—	1	—	4	—	3
Totals	69	45	9	2	84	47	

Historical and geographical readers are provided in every department, and even though the subject be not taken for the Government examination the children are always questioned on the matter of the reading-books by the Board's Inspector.

II. Specific subjects (scientific).

Subject		Departments 1882 Boys	1882 Girls	1884 Boys	1884 Girls
Algebra	Mathematics	4		13	1
Euclid and Mensuration				1	—
Mechanics		3	—	1	—
Animal Physiology		2	—	2	—
Botany		1	—	—	3
Domestic Economy		—	10	—	2
Totals		10	10	17	6

III. Science teaching under the Science and Art Department is given as follows :—

Subject	Departments Boys	Departments Girls
Mathematics	3	2
Physiology	1	1
Chemistry	3	2
Sound, Light, and Heat	2	2
Magnetism	2	2
Totals	11	9

The Brighton School Board had the following number of children studying the specific subjects during the quarter ending March 25, 1884 :—

	Boys	Girls
Algebra	285	—
Euclid and Mensuration	13	—
Animal Physiology	292	6
Magnetism and Electricity	149	—
Domestic Economy	—	261

As to class subjects, the ten boys' departments all take up geography as the second, the number of children under instruction being 2879; while only one girls' department, with 119 children, takes geography for the Government examination, though it is taught in most of the others through reading lessons. The other nine girls' departments, with 2339 children, take needlework as the second class subject. At the Southport meeting a recommendation was passed that this Committee "be requested to consider the desirableness of making representations to the Lords of the Committee of Her Majesty's Privy Council on Education in favour of aid being extended towards the fitting up of workshops in connection with elementary day schools or evening classes, and of making grants on the results of practical instruction in such workshops under suitable direction, and, if necessary, to communicate with the Council." As it was believed that the second Report of the Royal Commissioners on Technical Instruction would have an important bearing upon this question, the Committee was not called together till the publication of that Report. It was not issued till May, and it then appeared that, in addition to a very large amount of valuable information, the Royal Commissioners had recommended, among other things :—"(*b*) That there be only two class subjects instead of three in the lower division of elementary schools, and that the object lessons for teaching elementary science shall include the subject of geography." "(*d*) That proficiency in the use of tools for working in wood and iron be paid for as a specific subject, arrangements being made for the work being done, so far as practicable, out of school hours. That special grants be made to schools in aid of collections of natural objects, casts, drawings, &c., suitable for school museums." With reference to recommendation (*b*) your Committee, without expressing any opinion as to the desirability of forming one subject out of geography and elementary science, consider that, if this change be effected, the two class subjects which will then represent literature and science should stand upon an equal footing. This would be in accordance with the resolution of the Council passed on December 5, 1881, in considering the recommendations of your Committee in regard to the proposals for the new Code. At present, if only one class subject is taken, the Code requires that it should be "English" (grammar and literature); but many managers or teachers might prefer taking science. With respect to recommendation (*d*) your Committee thoroughly approve of the proposals, which, if carried out, would realise the wish expressed in the reference to them from the Southport meeting. They have not, however, thought it necessary to communicate at once with the Council, as there is no immediate legislation in prospect, and the meeting at Montreal might like to give further instructions on the subject. The name of Prof. N. Story Maskelyne, M.P., has been replaced on the Committee.

Report of the Committee, consisting of Sir Joseph Hooker, Dr. Günther, Mr. Howard Saunders, and Mr. P. L. Sclater (Secretary), appointed for the Purpose of Exploring Kilimanjaro and the Adjoining Mountains of Eastern Equatorial Africa.—(1) The Committee have the satisfaction of announcing that they have made arrangements with Mr. H. H. Johnston (who has recently returned from the Congo) to undertake an exploration of Kilimanjaro, and that he is probably by this time encamped upon that mountain. (2) The Committee have arranged with Mr. Johnston to undertake the cost of the expedition for 1000*l.*, without reference to personal remuneration. It is believed that the necessary expenditure will not be covered by this sum, but Mr. Johnston has agreed to make good any deficiency. (3) Towards this sum of 1000*l.* the Committee have appropriated a sum of 500*l.* granted to them by the Association at their last meeting at Southport. The Committee have also received from the Government Grant Committee of the Royal Society two sums of 250*l.* each, so that the whole sum of 1000*l.* required for the expedition is already available. (4) But looking forward to the risks of African travel, and to the expenditure likely to be incurred on the transport to this country, and on the working out of the collections obtained by Mr. Johnston, the Committee trust that a further sum of 50*l.* may be placed at their disposal. (5) A copy of part of Mr. Johnston's last letter to the Secretary of the Committee, containing an account of the progress of the expedition, is annexed to this Report.

Extracts from a letter from Mr. Johnston to Mr. Sclater, dated British Residency, Zanzibar, May 13, 1884 :—"At last my expedition, thanks to the help of Sir John Kirk, is organised and ready to start. I have engaged thirty-two men here (at Zanzibar), and have sent them off to Mombasa in a dow to await my coming. I myself leave to day for Mombasa in the mail. At Mombasa, through the Consul (Capt. Gissing), I have engaged sixty more men, for it will need nearly a hundred porters to carry my goods and baggage to Chagga. I hope to leave Mombasa in a fortnight's time. I anticipate three weeks' easy travel to Kilimanjaro, and, as far as it is possible to foretell aught in Africa, no serious difficulties seem to stand in my way. The expedition, however, will prove much more costly than I had anticipated. . . . However, I think I shall be able to make both ends meet for six months on Kilimanjaro, and if I stay longer, or make a dash at Kenia, it will be on my own account. I shall *probably* make Taita or Teita (*vide* map) a half-way house, and go backwards and forwards with collections and

goods. I shall try to forward collections addressed to you by *every mail* if feasible. Then, if you judge of the value, and estimate that my share of the collections will realise a good amount, it will induce me to devote more time to the country. My health, notwithstanding a much more trying climate than I have yet met with in Africa, has been very good, and I have not known an hour's illness or indisposition. Sir John Kirk has shown me the utmost kindness and hospitality, and his help and his influence have smoothed away many difficulties. The expedition promises most favourably, as the present condition of the countries to be traversed is good and peaceful, food abundant, and provisions cheap. . . . . I have obtained the services of three of Dr. Fischer's bird-skinners, and have got one botanical collector, trained under Sir John Kirk, and acquainted with the mysteries of 'soldering' and preserving in spirit. I have sent for rectified spirit from Bombay, and in the interval am using trade gin. The Sultan has given me three kegs of gunpowder to give as presents to chiefs, and has also furnished me with letters of introduction. I am in excellent condition, and start to-day on my journey in the best spirits and with the strongest hopes of its success."

Report of the Committee, consisting of Mr. James N. Shoolbred (Secretary) and Sir William Thomson, appointed for the Purpose of Reducing and Tabulating the Tidal Observations in the English Channel made with the Dover Tide-Gauge, and of Connecting them with Observations made on the French Coast.—The Committee beg to report that the tidal curves of the self-registering tide-gauge at Dover for the years 1880, 1881, 1882, and 1883, have been kindly placed at their disposal by the Board of Trade, for reduction and tabulation; and that the Belgian Government have been good enough to present to the Committee copies of the tidal curves at Ostend during the same period of four years. The reduction and tabulation of the high and low water registers of these two sets of tidal curves has progressed satisfactorily, and will be shortly completed. It is hoped also that a like reduction will be soon commenced with other self-registering tidal curves during the same period at several other points, both on the English and the French coasts. The Committee request to be allowed to transmit to the Board of Trade and to the Belgian Government respectively, the thanks of the Association for their assistance and donations in furtherance of this inquiry. The Committee request to be reappointed, with a grant of 10*l.* to defray the expenses of reduction, &c.

Report of the Committee, consisting of Prof. Balfour Stewart (Secretary), Prof. Stokes, Mr. G. Johnstone Stoney, Prof. Roscoe, Prof. Schuster, Capt. Abney, and Mr. G. J. Symons, appointed for the Purpose of Considering the Best Methods of Recording the Direct Intensity of Solar Radiation.—This Committee, acting on a suggestion made by Gen. Strachey, have chiefly devoted their attention to the subject of a self-recording actinometer. The self-recording actinometer of Mr. Winstanley would not be suitable,[1] because it is influenced by radiation from all quarters. Other actinometers require manipulation on the part of the observer which would make it almost impossible to make them self-recording. It was suggested by Prof. Balfour Stewart that a modification of his actinometer might be adapted to self-registration by taking for the quantity to be observed, not the rise of temperature of the inclosed thermometer after exposure for a given time, but the excess of its temperature when continuously exposed over the temperature of the envelope. After making some calculations as to the behaviour of such an instrument, Prof. Stokes came to the following conclusions:—(1) The inclosure should be of such a nature as to change its temperature very slowly, and of such a material that the various portions of the interior should be at the same moment of the same uniform temperature. For this purpose an arrangement somewhat similar to that used in Prof. Stewart's actinometer is suggested; the outside to consist of polished metallic plates, then a layer of some non-conducting substance, such as felt, then a thick copper interior which need not be polished. Into this copper is to be inserted a thermometer which will give the temperature of the copper interior from moment to moment.

[1] "This is the case at present, but there would not be any great difficulty in modifying it so as to act as required. It is quite a matter worth consideration whether a differential air-thermometer would not be very suitable, one bulb silvered and the other blackened or of green glass, as I suggested to the Meteorological Council some years back. By this means only *one* reading would be necessary, whilst in the plan suggested two would have to be recorded, and the measurements would be more difficult." (*Note by Capt. Abney.*)

(2) In the middle of the inclosure is to be placed the thermometer, upon which the heat of the sun is made to fall by means of a hole in the inclosure, either with or without a lens. This thermometer should be so constructed as to be readily susceptible to solar influences. It is proposed to make it of green glass (a good absorber and radiator), and to give it a flattened surface in the direction perpendicular to the light from the hole. Such an instrument should be so adjusted as to receive the sun's light continuously through the hole, and the objects of record would be the simultaneous heights of the two thermometers, the one giving the temperature of the inclosure, and the other of the central thermometer. There are two conceivable methods by which the necessary adjustment with regard to the sun's light might be secured, namely, (α) the inclosure might be subject to an equatorial motion so as to follow the sun, or (β) the inclosure might be kept at rest and the solar rays kept upon the hole by a heliostat. Capt. Abney is of opinion that the latter arrangement is, mechanically, much preferable to the former. As the direction of the earth's axis may be chosen as that into which the sun's light is to be reflected, a heliostat of a very simple construction will suffice; and as the angle of incidence on the mirror of such a heliostat changes only very slowly with the season, there is no difficulty in applying the small correction required for the change in the intensity of the reflected heat consequent on the change in the angle of incidence. It is assumed that the mirror of the heliostat is a speculum. It has been remarked by Gen. Strachey that some such instrument as this now suggested, even if not made self-recording, would have the advantage of giving an observation without the objectionable necessity of putting the light on for a given time, and then shutting it off, operations only suitable for trained observers. We think that it would be desirable to construct an inclosure with its two thermometers such as herein recorded. In all probability the loan of a heliostat and of an actinometer might be obtained. By aid of the heliostat the sun's light might be kept continuously upon the hole of the inclosure. The two thermometers would be read, and the results compared with the simultaneous reading of an ordinary actinometer. By such means it is believed that the best method of constructing such an instrument and observing with it might be found. We would therefore ask for a continuance of our Committee, with the sum of 30*l.* to be placed at our disposal for the purpose herein specified.

Report of the Committee, consisting of Mr. Sclater, Mr. Howard Saunders, and Mr. Thiselton Dyer (Secretary), appointed for the Purpose of Investigating the Natural History of Timor Laut.—Since our last report was presented to the Association, Mr. Forbes's botanical collection—which, from the result of an unfortunate fire in the drying-house in which the Herbarium had to be prepared, was very small, as he deplores—has been handed over to the Royal Herbarium at Kew. Of this collection Sir Joseph Hooker, at a meeting of the Royal Geographical Society on January 28, 1884, made the following remarks:—"From that time [of the appearance of Prof. Decaisne's 'Flora Timoriensis'] to this, the limits of the Australian flora, so long supposed to have been circumscribed with exactitude, have never been laid down, though it has been enormously enlarged to the north by the inclusion of the great island of Papua, which is to a great extent Australian in its biology, and by that of sundry other islets to the north-east and north-west. It is under this point of view that Mr. Forbes's collections are so important. It is true that for the most part they consist of what are generally known as *coral-island* plants. . . . But besides this there are some peculiar forms, and there are two plants of extraordinary interest which I would simply instance as being typical—one of the new Hebridean and one of the Australian flora. It so happened that these two plants belonged to unispecific genera. . . . The existence of these plants pointed to some old communication between these particular islands." No detailed account of the ethnographical collection has yet been published; but as the collection has been deposited in the British Museum, a description of the Timor Laut objects will doubtless appear in the Catalogue of the Ethnological Department, while the more interesting will be figured in Mr. Forbes's forthcoming volume. At the last meeting of the Association at Southport, Dr. J. G. Garson ("Report," p. 566) read a short account of the crania (now in the British Museum) brought from Larat by Mr. Forbes, which has been published *in extenso* in the *Journal* of the Anthropological Institute, vol. xiii., and which concludes with the following remarks on the relation of the inhabitants of

Timor Laut to those of adjacent countries:—"That the skulls just described are not those of a pure race is very evident. Two very distinct types can be made out, namely, the brachycephalic and the dolichocephalic, the former greatly predominating in number. Both from the information Mr. Forbes has given us as to their appearance, and from the skulls themselves, there is no difficulty in recognising a strong Malay element in the population. The male skull No. 4, and the female No. 6, are typically Malayan in their characters, especially in possessing large, open, rounded orbits, and smooth forehead, the superciliary ridges and glabella being almost entirely absent. The other brachycephalic skulls, though not presenting such a striking affinity, agree more or less with this type, but give evidence of mixed characters. The dolichocephalic skull is, on the other hand, markedly of the Papuan type, and corresponds so closely as to be undistinguishable from two crania obtained twenty miles inland from Port Moresby, New Guinea, in the College of Surgeons' Museum, also from another from the Solomon Islands. Along with this form of skull, Mr. Forbes informs me, is associated frizzly hair and dark skin. The examination of the cranial characters of the inhabitants of Timor Laut, as illustrated by the skulls before us, shows that the peopling of this island is no exception to what is usually found in the various groups of islands in the Polynesian Archipelago. From its close proximity to New Guinea, perhaps more of the Papuan element might have been expected." In addition, the *Coleoptera* sent home have been examined and described in a recent paper by Mr. C. O. Waterhouse, published in the Zoological Society's *Proceedings*. The number of species collected was twenty-nine; of these the following deserve special notice on account of their geographical distribution:—*Diaphates rugosus*, a new genus and species of *Staphylinidæ* known from Java; *Cyphogastra angulicollis*, only previously known from Banda; *C. splendens*, a new species allied to the preceding; *Archetypus rugosus*, belonging to a genus of Longicorns, of which there was only one species previously known, which species occurs in Waigiou, Dorey, and Aru; *Nemophas forbesii*, a new Longicorn nearly allied to *N. grayi* from Amboina. Further, a new species of ground thrush (*Geocichla machiki*) has been described by Mr. Forbes from additional specimens brought home by himself on his return. So that our knowledge of the avifauna of this region has been increased by the addition of twenty-four new species, entirely collected on the few square acres to which the inter-tribal wars of the natives restricted Mr. Forbes's operations. At the presentation of our last report, Mr. Forbes, who had just returned to England, gave a short description of the region visited by him; but at the meeting of the Royal Geographical Society, to which we have referred above, he gave a more detailed account, which has been published, illustrated by a map, in their *Proceedings* for March, embodying the geographical observations made by him. The collections of Fishes, Crustacea, and Hydrozoa, though containing much that was of interest, added few species that were new to science. A statement in our last report, on p. 227, that "the total expense of Mr. Forbes's expedition has amounted to 300*l*." ought perhaps to be corrected, as we understand from Mr. Forbes that the total cost was more than double this sum.

Report of the Committee, consisting of Mr. John Cordeaux (Secretary), Prof. Newton, Mr. J. A. Harvie-Brown, Mr. William Eagle Clarke, Mr. R. M. Barrington, and Mr. A. G. More, reappointed at Southport for the Purpose of Obtaining (with the Consent of the Master and Brethren of the Trinity House and the Commissioners of Northern and Irish Lights) Observations on the Migrations of Birds at Lighthouses and Light-vessels, and of reporting on the same.—The General Report[1] of the Committee, of which this is an abstract, comprises observations taken at lighthouses and light-vessels, as well as at several land stations, on the east coast of England, the east and west coasts of Scotland, the coasts of Ireland, also the Channel Islands, Orkney and Shetland Isles, the Hebrides, Faroes, Iceland and Heligoland, and one Baltic station on the coast of Zealand, for which the Committee is again indebted to Prof. Lutken of Copenhagen. Altogether 158 stations have been supplied with schedules and letters of instruction for registering observations, and returns have been received from 102. The best thanks of the Committee are due to their numerous observers for the generally careful and painstaking manner in which they have filled up the schedules, and the very intelligent interest taken by them in the inquiry. Special thanks must be accorded to Messrs. H. Gätke, Heligoland; H. C. Müller, Faroe; and M. Thorlacius, Skykkesholm, Iceland, for the notes sent in from their respective stations; also to Mr. J. H. Gurney, for having commenced on the south-east coast of England a similar system of inquiry, which, for a first trial, has worked well. In all doubtful cases of identity, where birds are killed against the lantern, a wing is cut off, and a label, with the date, attached. These have been forwarded in batches to Mr. Gurney for identification, and with most satisfactory results. The Committee regret that for the second year in succession they have received no report from the west coast of England. A late member of the Committee, Mr. Philip M. C. Kermode, having failed to make any returns, or to send the collected schedules, although repeatedly requested, to Mr. W. E. Clarke, who had undertaken the work of tabulating and reporting on the same, provision has been made by the Committee for supplying the deficiency in any subsequent years. The observations taken on the east coast of Great Britain in 1883 have been such as generally to confirm the conclusions arrived at in former reports, having reference to direction of flight and lines of migration. The winter of 1883-4 has been exceptionally mild, and there has been an almost entire absence of severe frosts and lasting snowstorms; the prevailing winds in the autumn, west and south-west, such as observation shows are most favourable for migrants crossing the North Sea and continuing their journey inland. Winds from opposite quarters to these tire out the birds and cause them to drop directly they reach land. Our land stations report a great scarcity both of land and sea birds; this has not, however, been the case at sea stations—that is, light-vessels moored off the coast at distances varying from five to fifty miles. Here the stream of migration, so far from showing any abatement, has flown steadily on in a full tide; and, if we judge from the well-filled schedules which have been returned, there has been a considerable increase in the visible migration, due perhaps in some measure to increased interest and improved observation. Mr. William Stock, of the Outer Dowsing light-vessel, remarks that he had never before seen so many birds pass that station; the rush, also, across and past Heligoland in the autumn was enormous. Migration is more marked, as well as concentrated, there, than at any station on the English coast. There was a great movement of various species passing forward on August 6 and 7, and again on the 14th, and more pronounced still on the 21st and 22nd, and on August 20 a similar movement was noticed at the Isle of May, at the mouth of the Firth of Forth. It was not, however, until September 21 and the two following days that the first great rush occurred on the English east coast, and a similar great movement or rush is indicated, at the same date, in Mr. Gatke's notes, as well as from the most distant of the lightships. The prevailing winds over the North Sea on September 21 were moderate north-easterly and easterly off the coasts of Denmark and Holland, blowing strong easterly on the coast north of the Humber, with southerly and south-westerly off the south-east coast, producing cross-currents over the North Sea. Whatever was the impulse, atmospheric or otherwise, which induced such a vast rush of various species at this time, it was one which acted alike, and with precisely the same impulse, on the sea-eagle and the tiny goldcrest. The second great rush was on October 12 and 13, a similar movement being recorded at Heligoland. Then, again, from the 27th to the 31st, and somewhat less through the first week in November, the passage across Heligoland, as well as the rush on our east coast, was enormous. Speaking of the nights from the 27th to the 31st inclusive, Mr. Gatke says: "This was the first move by the million; for four nights there has been a gigantic feathery tide running." During this time there were variable winds over the North Sea, but generally easterly and south-easterly on the Continent, strong west winds and squalls prevailing generally on November 5 and 6. Again, with the outburst of some severe weather in the first week in December, a considerable local movement is indicated along the coast from north to south, culminating in the enormous rush of snow-buntings into Lincolnshire about the end of the first week in that month. A careful perusal of the report will show how generally the rushes across Heligoland correlate with those on the east coast of England, although not always confined to identical species. A somewhat remarkable and very anomalous movement of migrants is recorded from light-vessels of the Lincolnshire and Norfolk coasts in the spring of 1883. In February, March, April, and May, birds passing the Leman and Ower, Llyn Wells, Outer Dowsing, Newarp and the Cockle light-
